$$D < D_{limit},$$

$$F_f = 250 \left[\frac{EAR}{Z} \right] [D]^2 \text{ kN} \quad (4)$$

$$D \geq D_{limit},$$

$$F_f = 500 \left(\frac{1}{1 - \frac{d}{D}} \right) H_{ice} \left[\frac{EAR}{Z} \right] [D] \text{ kN} \quad (5)$$

$$D_{limit} = \left(\frac{2D}{D - d} \right) \cdot H_{ice} \quad (6)$$

Polar Propulsion Design

Due to the special working environment of the polar ship, it is necessary to consider the influence of the environment, low temperature, and sea ice on the propulsion system. Therefore, the design of the polar propulsion system is different from the conventional propulsion system. The propulsion performance in ice conditions and open water conditions should be considered for the design work. Therefore, it is necessary to perform proper performance analysis under different navigation conditions during the propeller design process. In general, it is essential to determine whether the design of the blades meets the strength requirements according to the ice class rules. Due to the special requirements on strength, the blade section thickness of the ice class

propeller will be slightly thicker than that of the conventional propellers. In addition, the trailing edge of the propeller will become blunt in the rules for the radius of the guide circle. For such kind of propeller with a blunt trailing edge, the special blade section shape can cause a large pressure drag, resulting in a decrease in the propulsion efficiency. Usually, the propulsion efficiency of polar ship would be reduced by about 6% compared to a conventional propeller. The too low ambient temperature of the polar propulsion system determines the special design requirements of the main engine, ventilation system, and cooling water system. Thermal insulation measures for these systems need to be taken into account in the design to prevent the low-temperature environment from affecting its normal operation. In order to ensure that the polar ship can navigate in some areas where the noise level is limited, the designed propeller must also be optimized for radiated noise. Of course the propeller-ice contacting behavior could not be ignored; the shape of the blade must be specially designed so that the blade can effectively mill sea ice. The design of the ice class propeller must also be coordinated with the rational design of the hull lines to reduce the amount of sea ice flowing to the propeller. This would be helpful to avoid the blocking effect, noise, and cavitation effect.

Definition

Polar research vessel is a special kind of oceanographic research ships, which can also be seen as a special icebreaker.

Like most research vessels, polar research vessel has good control performance, improved the navigation and positioning system, and also is equipped with special equipment and instruments necessary for the execution of task. However, based on the geographical environment of the polar regions, polar research vessel should be able to work in harsh ice area for a long time.

Therefore, polar research vessels are constructed around an icebreaker hull, allowing them to engage in ice navigation and operate in polar waters. Due to most of ships cannot enter into the polar region, polar research vessels often play different roles.

Polar Regulations and Polar Research Vessel

At present, involving the polar shipping unified international rules mainly has two aspects. On the one hand, IACS has issued unified requirements for polar Marine, “Requirements Concerning Polar Class,” which is formulated by the nation classification societies jointly (IACS 2011). On the other hand, International maritime organization (IMO) issued a guide “International Code for Ships Operating in Polar Waters” in December 2002 (IMO 2013). On the basis of the guide, ships sailing in Antarctic waters are also

supplemented. The “Polar Code” was adopted in 2014 as a mandatory rule for polar sailing ships, which took effect on January 1, 2017.

The polar regulations regulate not only the ice grade, structure, stability, and seaworthiness of polar ships, but also the requirements for environmental protection. The regulations place strict limits on the polar regions, especially the Antarctic, and express trust in the polar research vessel. In other words, polar research ships are polar pioneers. She should fulfill her responsibilities and lead the trend of polar environmental protection and launch the polar green voyage.

Typical Polar Research Vessel

There are many famous polar research vessels in the world. Since the 1970s, the United States and the Soviet Union have begun to build. Nowadays, Russia have the largest number of polar ships. Japanese polar research vessel owns the comprehensive functions. The American polar star is one of the most famous polar scientific research vessels in history.

Polar Star

USCGC Polar Star (WAGB-10) is a United States Coast Guard heavy icebreaker. In 1976, the ship was built by Lockheed Shipbuilding and Construction Company of Seattle, Washington, along with her sister ship, USCGC Polar Sea ([USCGC Polar Star – History](#)). Now the polar star is the only heavy icebreaker in the United States, after the USCGC Healy was classified as a medium icebreaker.

Unique Ship Design

Polar Star (Baker and Jones 1998), which is shown in Fig. 1, uses four different methods of electronic navigation to overcome the difficulties of high-latitude operations, and a computerized propulsion control system to effectively manage six diesel-powered propulsion generators, three diesel-powered ship’s service generators, three propulsion gas turbines, and other equipment vital to the smooth operation of the ship. The extensive use of automation and low maintenance

Polar Research Vessel,
Fig. 1 The US coast guard
Polar Star

materials has greatly reduced staffing requirements.

Polar Star’s three shafts are turned by either a diesel-electric or gas turbine prime mover. This ensures her strong power. The combination of the hull and the reasonable internal structure endows the polar star very good structural strength. It is worth mentioning that the steel used in these structures has good low-temperature strength. In addition, Polar Star’s hull form is designed to maximize icebreaking by efficiently combining the forces of the ship’s forward motion, the downward pull of gravity on the bow, and the upward push of the inherent buoyancy of the stern. The curved bow allows Polar Star to ride up on the ice, using the ship’s weight to break the ice. Under the guarantee of these engineering techniques, polar star is able to break through ice up to 6.4 m thick by backing and ramming and can steam continuously through 1.8 m of ice at 3 knots. Polar voyages are difficult, so the Polar Star provides the crew with comfort living environment as much as possible.

General Characteristics

Class and type: Polar-class icebreaker
Displacement: 10,863 long tons (11,037 t) (standard)

(continued)

13,623 long tons (13,842 t) (full)		
Length: 399 ft (122 m)	Beam: 83 ft 6 in (25.45 m)	Draft: 31 ft (9.4 m)
Installed power: Six Alco 16 V-251F diesel engines (6 × 3,000 hp (2,200 kW))		
Three Pratt & Whitney FT-4A12 gas turbines (3 × 25,000 hp (19,000 kW))		
Propulsion: Combined diesel-electric or gas (CODLOG)		
Three shafts; controllable-pitch propellers		
Speed: 18 knots (33 km/h; 21 mph)		
3 knots (5.6 km/h; 3.5 mph) in 6-foot (1.8 m) ice		
Range: 16,000 nautical miles (30,000 km; 18,000 mi) at 18 knots (33 km/h; 21 mph)		
28,275 nautical miles (52,365 km; 32,538 mi) at 13 knots (24 km/h; 15 mph)		
Complement: 15 officers 127 enlisted 33 scientists		
12-person helicopter detachment		
Armament: 2 × 0.50 caliber machine guns Various small arms		
Aircraft carried: 2 HH-65A Dolphin helicopters		

Multiple Mission

Polar Star has a variety of missions while operating in polar regions. First of all, Polar Star serves as a scientific research platform with five laboratories and accommodations for up to 20 scientists. Researchers can do some work about fields of geology, volcanology, oceanography, sea-ice physics, and other disciplines which only be operated on a polar research vessel. Besides, the polar

research vessel is tasked with transporting supplies to polar research stations. For example, during Antarctic deployments, the primary missions include breaking a channel through the sea ice to resupply the McMurdo Research Station in the Ross Sea. Resupply ships use the channel to bring food, fuel, and other goods to make it through another winter. Last but not least, the polar research vessel sails and studies alone in the polar regions. Therefore, it is necessary for researchers on the polar research vessel to own strong self-survival and crisis management ability. It is also an important task to protect themselves and rescue other research vessels in distress.

Monumental Achievement

Polar Star was back in operation in late 2013, and assigned to Antarctic operations as part of Operation Deep Freeze in early 2014 (Boyle 2013). She was dispatched from Sydney on January 4, 2014, to attempt a rescue of the Russian research vessel Akademik Shokalskiy and Chinese icebreaking research vessel Xue Long trapped at that time in Antarctic ice, the former since 24 December 2013 (U.S. Breaker to Help Russian 2014; U.S. Coast

Guard Cutter Polar Star 2014). However, on January 8, 2014, the Australian Maritime Safety Authority confirmed that Polar Star had been released to scheduled duties as both vessels had broken free and were proceeding to open water (Antarctic Rescue Operations Complete 2014). In February 2015 Polar Star was involved in the rescue of the Australian fishing vessel Antarctic Chieftain, towing her and her 27 crew to safety, through ocean ice and snow nearly 20 feet deep in the Southern Ocean (<http://www.ktvz.com/news/us-coast-guard-icebreaker-frees-stuck-ship/31284578>). In February 2017, fire crews from the USCGC Polar Star were to made available to help the New Zealand Fire Service and NZDF Fire Crews in fighting against the Christchurch Port Hills Fires in Christchurch, New Zealand.

Shirase

New Shirase, as shown in Fig. 2 (Hull number: AGB-5003), was a new Japanese icebreaker operated by the Japan Maritime Self-Defense Force (JMSDF) and Japan's fourth icebreaker for Antarctic expeditions. She is the successor of the old Shirase (AGB-5002). They have the same name.

Polar Research Vessel, Fig. 2 The Japanese icebreaker Shirase

New Shirase was launched in April 2008 and was commissioned in May 2009. Since November 2009, She served in 51 Antarctic expeditions. She was able to move at three knots breaking 1.5 m of ice.

General Characteristics

Type: Icebreaker	
Displacement: 12650 t (standard) 20373 t (full)	
Length: 138 m (452 ft 9 in)	
Beam: 28 m (91 ft 10 in)	Draft: 9.2 m (30 ft 2 in)
Propulsion: Diesel-electric Four propulsion motors, 22,050 kW (30,000 hp) (combined)	
Two shafts; fixed-pitch propellers	
Speed: 19.5 knots (22.4 mph; 36.1 km/h) (max)	
Complement: Approx. 175 sailors + 80 researchers	
Aircraft carried: 3 helicopters	

The Development of Polar Research Vessel in Recent Years

Polar research vessels in new age mean more than ice-breaking capabilities, longer endurance, and better research facilities. At the same time, the new polar research vessel represents a greener

and more efficient energy source and more flexible ways to break ice.

RRS Sir David Attenborough (Planet Ice and the Dual-Functional 2017)

Design Characteristics

Tonnage: 15,000 GT (4,475 DWT)	
Length: 128.9 m (423 ft)	Beam: 24 m (79 ft)
Draught: 7 m (23 ft)	Depth: 11 m (36 ft)
Ice class: PC 4 (propulsion system PC 5)	
Installed power: 2 × Bergen B33:45L6A (2 × 3,600 kW) 2 × Bergen B33:45L9A (2 × 5,400 kW)	
Propulsion: Diesel-electric; two shafts 2 × 2,750 kW (Two 5-bladed controllable pitch propellers) + four Tees White Gill thrusters (2 bow + 2 stern ,4 × 1,580 kW)	
Two 5-bladed controllable pitch propellers	
Speed: 17.5 knots (32.4 km/h; 20.1 mph) (maximum) 13 knots (24 km/h; 15 mph) (cruising) 3 knots (5.6 km/h; 3.5 mph) in 1 m (3 ft) ice	
Range: 19,000 nautical miles (35,000 km; 22,000 mi) at 13 knots	
Endurance: 60 days Crew: 30 crew 60 scientists	
Aircraft carried: 1 helicopter	

The British Antarctic survey asks currently the UK Cammell Laird shipyard to build a new polar research vessel. “RRS Sir David Attenborough”

Polar Research Vessel, Fig. 3 RRS Sir David Attenborough

as shown in Fig. 3, which is used to replace “RRS Ernest Shackleton” and “RRS James Clark Ross” working in the south and the north Pole, expected to be delivered in 2019. The new polar research vessel costs about 200 million pounds. The ship is 128 m long and 24 m wide, owning a self-sustaining capacity of 60 days (polar region), and can carry more than 30 crew members and 60 scientists. Sir David Attenborough will have a twin-shaft hybrid diesel-electric propulsion system. The power plant, which can run with different configurations depending on the mission and operating conditions, produces electricity to two 2,750 kW (3,690 hp) asynchronous electric motors driving two 5-bladed controllable pitch propellers. At an economical cruising speed of 13 knots (24 km/h; 15 mph), she will have an operating range of 19,000 nautical 3D model diagram of RRS Sir David Attenborough miles (35,000 km; 22,000 mi). For maneuvering and dynamic positioning, the vessel will have four 1,580 kW (2,120 hp) Tees White Gill thrusters, two in the bow and two in the stern (Polar Research Vessel).

At 3kn speed, it can break 1 m ice, and the ice-class is PC4 (the propulsion system is PC5). The

ship is equipped with a large number of professional scientific research equipment and instruments and has advanced laboratories for Marine, submarine, and atmospheric research.

Researchers can collect the marine environment and biological data through the underwater robot and underwater glider, and at the same time, aerial robots and shipborne environmental monitoring systems can provide detailed polar environmental information. In order to meeting the increasing demands of scientific research, the laboratory space is designed to be reconfigurable and to be extended for building laboratory modules.

Xue Long 2

Xue Long 2, which is shown in Fig. 4, is a Chinese new generation of icebreaking research vessel that had entered service in 2019. She is named after Xue Long (China builds first polar research vessel 2018).

Design

Xue Long 2 measures 122.5 m (402 ft) long, with a beam of 22.3 m (73 ft) and a draft of 8.3 m (27 ft) at full load. She has a designed displacement of 13,996 tones (Xinhua 2017). She has a diesel-

Polar Research Vessel, Fig. 4 First icegoing picture of Xue Long 2

electric propulsion system, with two 16-cylinder and two 12-cylinder engines, both Wärtsilä 32-series designs, powering two 7.5 MW Azipods that give her a speed of up to 15 knots (17 mph) in open water and 2–3 knots (2.3–3.5 mph) when breaking ice. Xue long2 combines the technology, functional requirements, and environmental protection concept of the international new-generation research vessel. She adopts the internationally advanced hull form design with double directions icebreaking and owns a 360° Azimuth pod electric propulsion system, DP-2 dynamic positioning system, and capability of impacting ice to fragmentation. She can also realize the 360° free rotation in the polar region and break through the 20-m ice ridge in the polar region. In addition, the ship's maneuverability will be greatly improved, which can meet the navigation needs of the global unlimited navigation area. The structural strength meets the requirements of PC3, and the ice can be continuously broken at a speed of 2–3 knots on a 1.5 m thick ice layer covered with 0.2 m of snow. At the same time, the entire ship generator set is equipped with an exhaust gas cleaning system, focusing on the protection of the polar environment.

Furthermore, Xue Long 2 will be equipped with a smart ship system. It is the first time that China has equipped an intelligent Hull (China Classification Society (CCS) notation: i-ship H) system on a scientific research vessel. And it is also the first time that China has installed a smart Machinery (CCS notation: i-ship M) in an electric propulsion ship. This will effectively reduce the labor intensity of the crew and improve the operational efficiency of the ship.

Summarize the evolution of polar research vessel technology over the decades. The main development directions are as follows: hull design, auxiliary ice-breaking capacity, power plant, and hull form design with double directions icebreaking.

Polar Research Vessel Outlook and Conjecture

In this section, research and development with respect to the hull design, assist in ice breaking ability, power plant and doubling ice-breaking design are presented.

Hull Design

During the development of the polar research vessel for several decades, the complicated ice conditions brought her a lot of trouble. In order to adapting to the harsh ice conditions, polar research vessel need to have a larger displacement, a more reliable hull structure, and a longer range.

Assist in Ice Breaking Ability

In the last years, a variety of auxiliary ice-breaking systems have been developed to improve the ice-breaking capacity of polar research vessel. But these systems have only been applied to a few advanced ships and have not yet been popularized. Improvement and popularization of new technologies will make it possible to improve the working environment of polar research vessels.

Power Plant

Based on polar regulations and people's growing environmental awareness, we should search for more green energy. Similarly, we should also look for more powerful energy to support us to explore the polar regions. Both nuclear and electric power may be a direction for us, especially electrical propulsion.

Doubling Ice-Breaking Design

Doubling icebreaking is a very practical ice-breaker design for the ship with 360° azimuth propulsion units. The icebreaker with this design can not only use the bow to break ice, but also use the stern to break ice. The new technology of double icebreaking greatly enhances the maneuverability of the polar ship. When a polar ship possessing this design sails in the ice zone, she may take less time to turning around in ice area and she is less likely to get stuck in the ice layers.

LIMPET – Land Installed Marine Power Energy Transmitter; OWC – Oscillating water column; PTO – Power take-off; WEC – Wave energy converter

Definition

A power take-off of a wave energy converter is a mechanism with which the absorbed energy in the form of mechanical/pneumatic/potential energy from the primary energy conversion stage is transformed into useful mechanical energy for further energy conversion, mostly into electricity if a generator is connected to the PTO.

Scientific Fundamentals

Power Conversion Principle

For power conversion, it can be made using either translational or rotational motions and their corresponding PTO force or torque. When a translational motion is used for power conversion, the capture power by the PTO is calculated as

$$P = F_{pto} \cdot V \quad (1)$$

where F_{pto} is the force acting on PTO and V the velocity of the PTO for power generation.

When a rotary motion is used for power conversion, the power is given by

$$P = T_{pto} \cdot \omega \quad (2)$$

where T_{pto} is the torque acting on PTO and ω the angular velocity of the PTO for power generation.

From the formulae for power conversion, it can be easily seen that to generate a large power, two significantly different ways can be adopted:

- 1) Either with a very high (translational/rotational) speed but a small force/torque. Therefore, such a system tends to have a very high system reliability, and a high energy conversion efficiency (generally higher than 90% in conventional energy conversion) can be obtained. These can be seen in conventional power generation using steam turbines, which could directly generate electricity to grid (with frequency of 50 Hz or 60 Hz).
- 2) Or with a very large force when the velocity in the power convention system is low. These happened in most renewable energy converters in wind, tidal, and wave energy systems. Such systems tend to have a low reliability and low energy conversion efficiency. For wave energy conversion, a specific disadvantage is the reciprocating wave force and velocity (with a dominant period about 6–12 s for wave energy conversion (Falcao 2008; Sheng and Lewis 2016a)). The nature of wave energy conversion with a large force and a low speed (both are reciprocating in most cases) presents a serious engineering challenge in practical application in the following aspects:
 - System and component reliability: fatigue problems with stress concentration
 - Low energy conversion efficiency: directly linking to the initial capital of cost of energy production

Power Conversion

To convert the trapped energy by the WEC, different PTOs may be used, including linear PTOs

(direct drive or Wells turbine), nonlinear PTOs (impulse turbine), or coulomb PTO (hydraulic cylinder). For a simple linear PTO, the PTO force is proportional to the PTO displacement, velocity, and acceleration, given in an expression following (Babarit et al. 2012):

$$F_{pto} = M_{pto1}\ddot{x} + B_{pto1}\dot{x} + C_{pto1}x \quad (3)$$

where M_{pto1} , B_{pto1} , and C_{pto1} are constants, independent of the PTO displacement, velocity, and acceleration.

It is noted that only the damping term could extract a net power conversion, while other two terms could absorb energy in a part of the wave cycle, but they also feed energy back to wave in the other part of the wave cycle. As such, the overall net power is zero if the energy conversion efficiency is 100% or negative if the efficiency is less than 100%.

Wave Energy Conversion Maximization

PTO optimization for maximizing wave energy conversion for a given wave energy converter is a very important aspect when designing a wave energy converter and setting the relevant PTO parameters.

When examining the maximized wave energy absorption for a wave energy converter, it is generally accepted that the analysis on a linear system will give the correct information on how much wave energy can be converted by the device, since the maximized wave energy conversion for a given wave energy converter is same for both linear and nonlinear PTOs if the PTOs are optimized (see Sheng and Lewis 2016b). For this reason, the maximization of wave energy conversion by a wave energy converter can be simply carried out in frequency domain

$$\left[i\omega(\mathbf{M} + \mathbf{A} + \mathbf{M}_{pto}) + (\mathbf{B} + \mathbf{B}_{pto}) + \frac{1}{i\omega}(\mathbf{C} + \mathbf{C}_{pto}) \right] \mathbf{U} = \mathbf{F}_{ex} \quad (4)$$

where the bold letters in square bracket mean matrices and the letters with subscript *pto* correspond to the matrices for the power take-off system and $\mathbf{U}$ and $\mathbf{F}_{ex}$ are the complex vectors.

Following (Zheng et al. 2016a; Evans 1981; Falnes 1999), the average absorbed power from wave can be given as

$$\bar{P} = \frac{1}{4} (\mathbf{F}_{ex}^* \mathbf{U} + \mathbf{U}^* \mathbf{F}_{ex}) - \frac{1}{2} \mathbf{U}^* \mathbf{B} \mathbf{U} \quad (5)$$

where the asterisk $*$ means the conjugate of the complex vector. This formula indicates that the converted average power $\bar{P}$ equals the gross power due to the equivalent excitation force, $\mathbf{F}_{ex}$, less the power due to the wave radiations.

The equation can be further written as

$$\begin{aligned} \bar{P} = & \frac{1}{8} \mathbf{F}_{ex}^* \mathbf{B}^{-1} \mathbf{F}_{ex} \\ & - \frac{1}{2} \left(\mathbf{U} - \frac{1}{2} \mathbf{B}^{-1} \mathbf{F}_{ex} \right)^* \mathbf{B} \left(\mathbf{U} - \frac{1}{2} \mathbf{B}^{-1} \mathbf{F}_{ex} \right) \end{aligned} \quad (6)$$

This could lead to an overall maximized wave energy conversion:

$$\bar{P}_{MAX} = \frac{1}{8} \mathbf{F}_{ex}^* \mathbf{B}^{-1} \mathbf{F}_{ex} \quad (7)$$

under the following constraint for an optimal velocity:

$$\mathbf{U}_{opt} = \frac{1}{2} \mathbf{B}^{-1} \mathbf{F}_{ex} \quad (8)$$

The condition implies that the overall maximal wave energy conversion happens at the resonance of the dynamic system with the PTO damping equalling to the radiation damping. The explanation is given as follows.

The solution of Eq. (4) can be simply expressed as

$$\mathbf{U} = \left[i\omega(\mathbf{M} + \mathbf{A} + \mathbf{M}_{pto}) + (\mathbf{B} + \mathbf{B}_{pto}) + \frac{1}{i\omega}(\mathbf{C} + \mathbf{C}_{pto}) \right]^{-1} \mathbf{F}_{ex} \quad (9)$$

When in resonance, the following condition must be satisfied:

$$\omega^2(\mathbf{M} + \mathbf{A} + \mathbf{M}_{pto}) - (\mathbf{C} + \mathbf{C}_{pto}) = 0 \quad (10)$$

When the system is in resonance, the velocity is given as

$$\mathbf{U} = (\mathbf{B} + \mathbf{B}_{pto})^{-1} \mathbf{F}_{ex} \quad (11)$$

Although the matrices $\mathbf{B}$ and $\mathbf{B}_{pto}$ are both real matrices, Eq. (11) cannot be simply interpreted as the optimal velocity $\mathbf{U}$ is in phase with excitation $\mathbf{F}_{ex}$. However, if the single motion mode is for wave energy conversion, the velocity is indeed in phase with the excitation. Hence the resonance condition is called as the phase optimal condition.

Taking $\mathbf{B}_{pto} = \mathbf{B}$ as the amplitude control, Eq. (11) is same as Eq. (8), a condition corresponding to the maximal wave energy absorption, given by Eq. (7). This optimal PTO damping level is the amplitude optimal condition.

The maximization of energy absorption by a wave energy converter above actually provides the basic principle for control technologies on how to achieve the maximized wave energy absorption: in regular wave, it can be done simply by adjusting PTO's $\mathbf{M}_{pto}$ and/or $\mathbf{C}_{pto}$ to make the dynamic system in resonance with the wave excitation to achieve the optimal phase control, while by setting the PTO's damping level, it is possible to attain the optimal amplitude control (Falnes 1995).

When the phase and amplitude are both optimally controlled, the control is optimal. When only the phase or the amplitude is optimized or partially optimized, the control is suboptimal. In reality, suboptimal controls may be more realizable due to less strict constraints.

PTO Optimization

Fix-referenced WECs (One Motion Mode)

The simplest case would be the fix-referenced wave energy converters where a single motion mode is accounted for wave energy conversion, such as the fix-referenced point absorber using

heave motion (Seabased 2015; CETO Rafiee and Fievez 2015, etc.), the bottom-fixed oscillating surge wave energy converter using the pitch of the flap (Oyster Whittaker and Folley 2012), or the bottom-fixed OWC device, using the heave motion of the fluid in the water column (LIMPET Folley et al. 2006). For such simple devices, the analytical PTO optimization can be easily derived (see Falnes 2002; Sheng and Lewis 2012).

Taking a fix-referenced point absorber as an example, its heave motion is used for wave energy conversion, and the solution of the dynamic system is simply given as

$$U_3 = \frac{F_{ex3}}{i\omega(M + A_{33} + M_{pto}) + (B_{33} + B_{pto}) + \frac{1}{i\omega}(C_{33} + C_{pto})} \quad (12)$$

where subscript "3" means the heave motion following the convention in the boundary element method.

The average wave energy absorption by the PTO is

$$\bar{P} = \frac{1}{2} B_{pto} \frac{|F_{ex3}|^2}{(B_{33} + B_{pto})^2 + [\omega^2(M + A_{33} + M_{pto}) - (C_{33} + C_{pto})]^2} \quad (13)$$

The maximal power absorption happens when

$$B_{pto} = \sqrt{B_{33}^2 + \omega^2 \left[(M + A_{33} + M_{pto}) - \frac{1}{\omega^2} (C_{33} + C_{pto}) \right]^2} \quad (14)$$

The maximal average power is calculated as

$$\bar{P}_{\max} = \frac{1}{4} \frac{|F_{ex3}|^2}{B_{33} + \sqrt{B_{33}^2 + [\omega^2(M + A_{33} + M_{pto}) - (C_{33} + C_{pto})]^2}} \quad (15)$$

When the point absorber is in resonance with incident wave, a condition must be satisfied:

$$\omega^2(M + A_{33} + M_{pto}) - (C_{33} + C_{pto}) = 0 \quad (16)$$

we have from Eqs. (14) and (15) as

$$B_{pto} = B_{33} \quad (17)$$

$$\bar{P}_{MAX} = \frac{1}{8} \frac{|F_{ex3}|^2}{B_{33}} \quad (18)$$

Eq. (18) is a special case of Eq. (7) when a single motion mode is used for wave energy conversion.

Self-Referenced WECs (Multiple Motion Modes)

For massive wave energy production, the wave energy converters may be more likely deployed in the relative large water depth (larger than 50 m) where the wave energy resources are better, and it is more economic for floating wave energy devices. As such, they may use multiple motion modes or relative motions for wave energy conversion.

When the relative motion from two motion modes is used for wave energy conversion, the analytical PTO optimization can be still obtained (Falnes 1999) and Sheng et al. (Sheng and Lewis 2016b). Taking the relative heave motion of two bodies as the motion for wave energy conversion as seen in OPT and RM3 floating point absorbers, the dynamic equation is

$$\begin{cases} \left[i\omega(m_{33} + a_{33}) + b_{33} + \frac{c_{33}}{i\omega} \right] v_3 + \left[i\omega a_{39} + b_{39} + \frac{c_{39}}{i\omega} \right] v_9 = f_3 - B_{pto}(v_3 - v_9) \\ \left[i\omega a_{93} + b_{93} + \frac{c_{93}}{i\omega} \right] v_3 + \left[i\omega(m_{99} + a_{99}) + b_{99} + \frac{c_{99}}{i\omega} \right] v_9 = f_9 + B_{pto}(v_3 - v_9) \end{cases} \quad (19)$$

where m_{33} and m_{99} are the mass of the bodies; a_{33} , a_{39} , a_{93} , and a_{99} the added mass coefficients; b_{33} , b_{39} , b_{93} , and b_{99} the potential damping coefficients; c_{33} , c_{39} , c_{93} , and c_{99} the restoring force

coefficients; f_3 and f_9 the complex heave excitation force amplitudes of two bodies; and v_3 and v_9 the complex heave motion velocity amplitudes of the two bodies.

$$\begin{pmatrix} i\omega(m_{33} + a_{33}) + (b_{33} + B_{pto}) + \frac{c_{33}}{i\omega} & i\omega a_{39} + (b_{39} - B_{pto}) + \frac{c_{39}}{i\omega} \\ i\omega a_{93} + (b_{93} - B_{pto}) + \frac{c_{93}}{i\omega} & i\omega(m_{99} + a_{99}) + (b_{99} + B_{pto}) + \frac{c_{99}}{i\omega} \end{pmatrix} \begin{pmatrix} v_3 \\ v_9 \end{pmatrix} = \begin{pmatrix} f_3 \\ f_9 \end{pmatrix} \quad (20)$$

Once the dynamic equation is solved, the average power absorption is given as

$$\bar{P} = \frac{1}{2} B_{pto}(v_3 - v_9)(v_3 - v_9)^* \quad (21)$$

Both Falnes (1999) and Sheng et al. (Sheng and Lewis 2016b) have given the expressions for the optimized B_{pto} and the corresponding average power $\bar{P}$. Obviously, the detailed expressions are

much more complicated than those in a single motion mode for wave energy conversion (the complicated mathematical expression and derivation can be found in (Sheng and Lewis 2016b; Falnes 1999)).

For more general cases with multiple motion modes, the analytical PTO optimizations are more complicated. In fact, they can be made only in some special cases (more details can be found in Pizer (1993) and Zheng et al. (2016b)).

PTO Optimization for Irregular Waves

The PTO optimizations mentioned above are valid only for regular waves. In irregular waves, they can be regarded as a combination of many different regular components of different amplitudes, frequencies, and phases, and for each wave cycle, its period and height are different. To achieve an optimized PTO damping for a given sea state, the trial-and-error method is usually used. For instance, Bull (2014) suggested 200 different damping levels are used to try out the optimized PTO damping for the RM3 BBDB OWC wave energy converter, while Sheng et al. (Sheng and Lewis 2016b) suggested that using T_e as a reference wave period for the irregular waves to calculate optimized PTO damping (same method as for regular waves) and the search of the optimized PTO damping levels could be close to the one based on the reference period of T_e . As such, the optimized PTO damping can be more easily found.

Key Applications

Types of PTO

For different types of wave energy converters, the primary converted energy can be in different forms: in the oscillating water columns, it is pneumatic power trapped in the air chamber in the

OWC devices, the potential power in the overtopping devices or the kinetic power of the body (or bodies) in the oscillating body (bodies) wave energy converters (see Fig. 1). To convert the different forms of the primary converted energy, different types of PTOs are employed: for pneumatic power, it is an air turbine, such as the Wells turbine and impulse turbine (Fig. 2a (Falcao and Gato 2012)); for potential energy, low head water turbines are used (Fig. 2b, the Kaplan low head water turbine in Wave Dragon (Kofoed et al. 2005)); while for the body kinetic power, hydraulic PTO (Fig. 2c, Falcao 2010) or the direct drive PTO (Fig. 2d, Drew et al. 2009) can be used. These PTOs may be the most used PTO technologies, but we should not exclude other types of PTOs, for instance, the mechanical PTO and the recent PTO developments supported by WES (Wave Energy Scotland 2015).

Control Technologies

Control technologies for wave energy converters have been a hot and interesting topic of research work since the principle of the optimal control for improving wave energy absorption was identified in the 1970s (Budal and Falnes 1977), and since then researchers have been seeking different control technologies to solve the problems of low wave energy conversion efficiency, especially for those small devices (small devices have been

Power Take-Off System,

preferred due to their robustness in structure, and also the smaller the device, the higher the ratio of the capture power over the mass according to (Falnes 2002)). A good review on controls for improving wave energy conversion can be found in (Ringwood et al. 2014).

In the previous sections, it has been shown that the maximum energy absorption by a wave energy converter occurs when the device is in resonance. To maximize wave energy conversion, the PTO control system could provide an additional mass or a negative spring to change the converter resonance period, i.e., the wave energy system has a

cancelled intrinsic impedance. More specifically, with setting or changing of the PTO parameters (i.e., the PTO control, see Eq. (3)), the maximal wave energy conversion can be achieved through the device resonance with the incident wave and the optimal damping level of PTO (Evans 1981; Falnes 1980). While in regular waves such an optimal control may be very straightforward, it becomes much more complicated in irregular waves since every wave cycle in irregular waves has different frequencies and amplitudes, and it is practically unknown what would be in the next wave cycle. This applies a challenge for the

control systems since they need the future information to decide the control parameters and to allow the time for the system to make the control. For instance, a latching control through peak-matching requires the information when is the peak in the future. As shown in (Fusco and Ringwood 2012), most of the active control system needs the future information of a time horizon more than 20s, and an accurate prediction of such a long time horizon is really challenging. This essentially becomes one of two barriers in practical control applications for many wave energy converters controls (the other barrier is the physical implementation of the control system, for instance, how the control system provides the required inputs of large forces to make the control working. In (Hals et al. 2011), these two challenges are specially attributed to latching control, but in fact, they are the common challenges for most control technologies: to make the control optimal, the required future information must be known to the control algorithms, and an ideal control system may be required to provide a large force in a rather swift manner). To remove the barriers partially or fully and make the control more practical, different control technologies have been proposed and attempted. For instance, Falcao (2007) and Sheng et al. (2015) developed the different latching control technologies. In these two novel latching controls, the controllers lock the devices when the device motion velocity vanishes, which are same as in conventional latching control technologies, but both latching controls remove the requirement of the future event prediction. In the former method, it is proposed to release the device when the excitation force is larger than a preset threshold, while in the latter method, a simple latching duration is calculated based on the wave statistics (the wave statistics can be reliably forecast hours ahead of real time or calculated from the wave measurement of the last 30 or 60 min. It is generally accepted that wave statistics may not change in 3 h or a longer period). As such, the barrier for requiring the prediction of the future information is removed!

To date, many different types of control technologies have been proposed and studied, and

more are being proposed and/or developed. Ozkop and Altas (2017) have reviewed the literature and summarized that more than 30 different type control technologies. The most popular controls in the summary include (short names in the brackets) following the popularity order in the reference: phase control (PhC), latching control (LC), optimal control (OC), PI control (PIC), predictive control (PC), on-off control (OOC), power control (PoC), valve control (VC), reactive control (RC), etc. It should be seen that although different names are used in the control technologies, some of them may be same in principle. Strictly speaking, a full optimal control (OC) is the ultimate goal for all control technologies, by achieving both the phase and amplitude control conditions, such as the predictive control (PC), which is essentially seeking the optimal conditions in the control method. Alternatively, sub-optimal conditions are made. For instance, many control technologies are implemented the full or partial phase optimal conditions, including the phase control (PhC), reactive control (RC), latching control (LC), on-off control (OOC), etc.

In a rather detailed comparison, Hals et al. (2011) present a conventional optimized resistive loading (RL) and five popular wave energy control technologies. The former is essentially an optimized PTO damping for the given waves, which provides a base for comparison. The compared control technologies include the classic phase control by (i) latching (Falcao 2008; Babarit and Clement 2006) and (ii) clutching (Babarit et al. 2009) and the advanced active controls, (iii) the approximate complex-conjugate control (Nebel 1992), (iv) tracking of approximate optimal velocity (Falnes 2002), and (v) model predictive control (MPC) (Cretel et al. 2011; Brekken 2011). From the comparisons, it can be seen that all the controls are superior to the pure optimized PTO resistive loading (RL), with the MPC control being the best control since in all the compared cases, MPC gives highest energy conversion, generally 200% more capture energy when compared to RL, and also for longer waves, the controls could produce more wave energy. It should be noted that the comparisons are made for wave energy period $T_e = 6$ s, 9 s, and 12 s, all longer

than the natural period of the semisubmersed sphere, $T_0 = 4.4$ s.

Definition

Deep-sea mining system is a system that can excavate, collect, and transport minerals from the seabed to the mothership (Liu et al. 2014).

System Brief Introduction

The system that combines deep-sea mining vehicles with pipeline transportation system is widely regarded as the most promising commercial mining system at the moment. This mining system is mainly composed of deep-sea mining vehicle,

mineral transportation system, surface support system, power transmission, and control system. The power transmission system mainly provides the power for deep-sea mining vehicles, mineral transportation system, and surface support system. It is an important part of the whole mining system and is the basic condition of whether the whole mining system can work properly. It can be regarded as the “nervous system” of the mining system, so it requires very high reliability.

Figure 1 shows a typical mining system.

Surface Support System PTD

Surface Support System Composition

The surface support system is mainly composed of the following equipment:

- Mining vehicle launch and recovery system.
- Umbilical launch and recovery system.

Power Transmission and Distribution, Fig. 1 Typical mining system

- Flexible pipe launch and recovery system.
- Heave compensation system.
- Pipe lift system.
- Pipe storage and transfer system.
- Pipe docking and disassembly system.

Surface Support System Power Requirements

There are several kinds of electrical equipment voltage of surface support system: three-phase AC690 V, three-phase AC380 V (50 Hz) or AC440 V (60 Hz), and single-phase AC220 V. These types of voltage can be output directly by the ship generator, and the distance from the ship's distribution cabinet to the electrical equipment is not very far so low voltage can be used directly for power transmission.

Underwater PTD System

The power transmission and distribution equipment of the underwater mineral transportation system and mining vehicle covers a large area and is usually installed on deck, but it can't meet the waterproof requirements if directly installed on the deck. Also it is dangerous to expose the high-voltage equipment on the deck, so it is required to be installed in a container with a protection grade of at least IP65.

The output of ship generator is usually AC low voltage, while the input voltage of underwater motor is generally AC high voltage, so the ship electrical output needs to pass through a step-up transformer to obtain the high voltage required by the motor. The voltage of underwater instruments and control systems are usually AC220 V, AC110 V, DC24 V, and DC5 V. These equipment power can't be transported directly through the low voltage so it also needs to be transported

through high voltage. The high voltage is converted to the required AC220 V and AC110 V under the water. The DC24 V and DC5 V are available from AC110 V via PSU.

For lift pump, hose pump, and mining vehicle, the starting current of the motor is large, so soft start equipment is needed. The lift pump needs to adjust speed so frequency converter soft start is needed. The high-voltage frequency converter covers a large area so it is not suitable to install in the container. We can choose the low-voltage frequency converter. The motor of hose pump and mining vehicle has no speed regulation requirement, so we can choose low-voltage thyristor soft starter for economic reason. Buffer station hydraulic station motor power is small and can start directly. The input power from ship is connected to the step-up transformer through the frequency converter or soft starter, and the high-voltage output terminal of the transformer is connected to the outlet box in the container through the high-voltage cable. The high-voltage power and communication fiber is combined together in the outlet box and then connected to the slip ring in the umbilical winch through umbilical. The power is transported to the underwater motor by umbilical via slip ring.

Figure 2 is a road map of underwater equipment power supply, and Fig. 3 is a schematic diagram of underwater equipment power supply.

Key Technology of Underwater PTD

Deep-Sea Long-Distance High- Efficiency PTD Technology

Ship power supply is different from land power supply; the electric power is supplied by ship generators. The power network capacity is generally small and has poor impact resistance. Heavy

Power Transmission and Distribution, Fig. 2 Road map of underwater equipment power supply

Power Transmission and Distribution, Fig. 3 Schematic diagram of underwater equipment power supply

use of nonlinear loads on ships results in a large number of harmonics. It not only seriously affects the power quality of the ship power grid but also interferes the normal operation of other electrical equipment. The current generated at the start of high-power load is as high as four or seven times the rated current; it will have a huge impact on the ship power grid when it starts. On the other hand, because the underwater equipment can work at a depth of 6,000 m (Wang and Wang 2007), such a long-distance transmission of electric power will cause a serious voltage drop of the line, and this will make the motor not stop because the start voltage is too low. Therefore, how to ensure the reliable transmission of underwater electric power over a long distance needs serious consideration. In addition, the underwater load is far away from the power supply, the transmission loss will be very high if the current is too large. But if the voltage is too high, there will be some problems in the manufacture of umbilical. So there are many factors that need to be considered in selecting the transmission voltage level.

Online Monitoring and Diagnosis Technology for Insulation and Grounding Circuit of Deep-Sea Circuit

Whether the key components such as power supply, umbilical, and transformer can work normally will directly affect the safe and reliable operation

of transmission and distribution system. Most of the insulating materials are organic materials, which are prone to deterioration due to various factors such as electricity, heat, machinery, environment, and so on, resulting in insulation aging, especially in the harsh environment of the ocean, which is very corrosive and complex. Therefore, it is necessary to have a set of reliable scheme to monitor the equipment insulation and line grounding condition in real time so as to detect power supply failure in time, avoid endangering personal safety, and ensure the safe and reliable operation of the whole system.

Development of Deep-Sea Optoelectronic Composite Umbilical

Deep-sea optoelectronic composite umbilical is the “nerve and lifeline” of underwater system; it connects electrical equipments on ship and underwater production facilities to transmit the ship power and all communication signals to deep-sea mining equipment. In the deep sea, the umbilical is affected by the chemical corrosion of sea water, ocean current movement, sea bottom biological impact and bite, and gravity of relay stations and mining vehicles, which can easily cause functional units and tensile failure. So it's important to develop high reliability and long life cycle composite umbilical.

Binding Technology of Umbilical

The umbilical that transmits power to the lift pump and buffer station must be bound and fixed on the pipe; otherwise the umbilical will swing violently under the influence of the current, which will not only produce a huge pulling force on the winch and the underwater connection box on the ship. It will also collide violently with the delivery pipe, which will easily lead to the breakage of the umbilical. The binding scheme should meet the requirements of fast operation on ship, and the binding material should be corrosion-resistant in sea water, have enough friction to fix itself on the pipe, and have enough load bearing capacity to hold the umbilical.

Underwater PTD Mode

The main load of underwater system is lift pump motor, buffer station hose pump motor and hydraulic station motor, and mining vehicle motor. Motor power of lifting pump and mining vehicle is very high, for example, the power of lifting pump motor is 800 kW in the Korean mining experiment project, and the power of mining vehicle motor is 550 kW. The power of underwater mining vehicle motor is even more than several MW in the mining system of Nautilus Mining Company of Canada. The water depth of deep-sea mining is generally more than 1000 m. For example, the “Blue Nodule” project in Europe is

Power Transmission and Distribution, Table 1 Comparison of different transmission modes

Sequence number	Index name	AC low voltage transmission	AC high voltage transmission	DC high voltage transmission
1.	Line current	Very big	Small	Small
2.	No load voltage drop	Big	Small	Very small
3.	Full load voltage drop	Very big	Small	Small
4.	Terminal voltage control	Complicated	No	Complicated
5.	Line reactive capacity	Common	Common	No
6.	Transmission distance	Near	Far	Far
7.	Transmission cable number	3 for 3 phase or 2 for single phase	3 for 3 phase or 2 for single phase	2
8.	Transmission cable diameter	Very big	Small	Small
9.	Transmission voltage level	Low	High	High
10.	Transmission starting equipment	No	Step-up transformer	Step-up transformer and rectifier
11.	Transmission terminal equipment	No	No or step-down transformer	Underwater inverter or inverter and rectifier
12.	Line loss	Very big	Small	Small
13.	Equipment area	Small	Small	Big
14.	Technology reliability	High	High	Common
15.	Technology maturity	High	High	Common
16.	Transmission cable cost	High	Low	Very low
17.	Transmission equipment cost	Low	Common	High
18.	Maintenance	Simple	Relatively simple	Complicated

designed with a maximum depth of 6000 m, and four lifting pumps are used. If we use the low voltage from the ship generator to the transmission of such a long distance of high power, the current will be very large and the line voltage drop will be severe, and the underwater motor will not be able to start. Table 1 is the comparison of three common modes of high electric power transmission in long distance.

As can be seen from the above table, when the three-phase or single-phase underwater equipment is in long-distance, high-capacity transmission, the AC high-voltage mode is the best scheme. The transmission mode is simple, the efficiency is high, the cost of transmission equipment is relatively low, and the technology is mature. So the input voltage of deep-sea motor is generally three-phase AC300 0 V at present, while the higher power motor can use three-phase AC600 0 V.

Underwater Motor Start Mode

The capacity of the ship power supply network is very small compared with the land power supply network. The starting current of the high-power motor is very large when it starts directly which will have a serious impact on the whole ship power supply, so the underwater motor should choose the proper starting mode. There are several general starting methods of AC motor as follows: frequency converter start, thyristor soft start, and direct start. Table 2 is the comparison of three different motor start methods.

As can be seen from above table:

- (a) Direct start has a great influence on input power supply so it is only suitable for low power motor.
- (b) It is necessary to use thyristor or frequency converter to start the heavy-duty motor so as to reduce the impact on the ship power grid.

Power Transmission and Distribution, Table 2 Comparison of different motor start methods

Sequence number	Index name	Frequency converter start	Thyristor soft start	Direct start
1.	Start current	Small	Small	Can be as big as 4 to 7 times rated current
2.	Start torque	Big	Small	Big
3.	Applicable load	All loads	Light load or no load	Big system
4.	Output voltage	Continuous adjustable	Continuous adjustable	Can't adjust
5.	Output voltage harmonic	Low	High	No
6.	Input power factor	High	Common	Low
7.	Influence on ship power	Low	Common	Big
8.	Speed regulation function	Yes	Yes	No
9.	Speed regulation performance	Excellent	Common	No
10.	Control difficulty	Complicated	Simple	Simple
11.	Area	Big	Small	Small
12.	Reliability	High	High	High
13.	Maturity	High	High	High
14.	Cost	High	Common	Low
15.	Maintenance	Complicated and high cost	Relatively simple and common cost	Simple and low cost

- (c) We can use frequency converter to start and control speed when the heavy-duty motor has speed regulation requirement.

The motor of the lifting pump has a large power and needs to adjust the speed according to the working conditions so it is suitable to start with the frequency converter. Relay station hose pump motor and mining vehicle motor have a large power but do not need to adjust the speed so it is suitable to start with thyristor soft start. Relay station hydraulic station motor power is small so it can start directly.

PTD Equipment

PDU

PDU is used to switch on and switch off the circuit; it also can show the circuit parameters such as voltage, current, power, and so on. A PDU mainly contains breaker, contactor, meters, protection devices, and other auxiliaries. Breaker is a kind of switchgear which can not only turn on and off normal load current and overload current but also switch on and off short circuit current. In PTD system, there are two types of breakers widely used, molded case circuit breaker and air circuit breaker. Molded case circuit breaker rated voltage from AC38 0 V to AC69 0 V and rated current from 16A to 1600A. Air circuit breaker rated voltage from AC38 0 V to AC115 0 V and rated current from 630A to 6300A. Figure 4 shows a PDU. Figures 5 and 6 are typical molded case circuit breaker and air circuit breaker.

Contactor is a kind of electrical appliance used to switch on and break AC/DC main circuits and large capacity control circuits frequently, rated current from 9A to 2600A and rated voltage from AC22 0 V to AC100 0 V. Figure 7 shows a typical contactor.

Transformer

Transformer is a device that uses the principle of electromagnetic induction to change the AC voltage. The main components are primary coil, secondary coil, and iron core. Main functions are

Power Transmission and Distribution, Fig. 4 PDU

voltage conversion, current conversion, impedance conversion, isolation, voltage stabilization, etc. There are generally three types of transformers used in deep-sea mining system. One is three-phase or single-phase step-up transformer to convert the low voltage from ship generator into high voltage required for underwater equipment. One is single-phase transformer to convert single-phase high voltage that transported to underwater into single-phase low voltage. One is low-voltage transformer which converts the low voltage from ship generator into other required low voltage. Figures 8, 9, and 10 show typical transformers of these three types.

Current Transformer

Current transformer is an instrument for measuring primary side high current via secondary side small current according to the electromagnetic induction principle. It is composed of closed iron core and winding. Low-voltage current transformer and high-voltage current transformer are

Power Transmission and Distribution, Fig. 5 Molded case circuit breaker

Power Transmission and Distribution, Fig. 6 Air circuit breaker

Power Transmission and Distribution, Fig. 7 Typical contactor

Power Transmission and Distribution, Fig. 8 Three-phase step-up transformer

commonly used in power transmission and distribution system. Figures 11 and 12 are typical low-voltage current transformer and high-voltage current transformer.

Power Transmission and Distribution, Fig. 9 Single-phase step-down transformer

Power Transmission and Distribution, Fig. 11 Low-voltage current transformer

Power Transmission and Distribution, Fig. 10 Low-voltage transformer

Power Transmission and Distribution, Fig. 12 High-voltage current transformer

Potential Transformer

Potential transformer is an instrument used to convert the primary side high voltage of the line into the standard low voltage of the secondary side. It is used to measure the line high voltage via the secondary side low voltage. Figure 13 is a typical potential transformer.

Frequency Converter

Frequency converter is a kind of electric power control equipment which uses frequency

Power Transmission and Distribution, Fig. 13 Potential transformer

conversion and microelectronic technology to control AC motor by changing the frequency of motor working power supply. Frequency converter is mainly composed of rectifier, filter, inverter, brake unit, drive unit, detection unit, micro-processing unit, and so on. Frequency converter adjusts the voltage and frequency of output power supply by switching on and off internal IGBT. It provides the required power supply voltage according to the actual needs of motor, thus achieving the purpose of saving energy and adjusting speed. Figure 14 shows the typical low-voltage frequency converter.

Soft Starter

Soft starter is a kind of motor control equipment which integrates soft start, soft stop, light-load energy-saving, and multifunction protection. The soft starter uses a three-phase opposite parallel thyristor as a voltage regulator and connected between the power supply and the motor stator. When starting the motor with soft starter, the output voltage of the thyristor increases gradually, the motor accelerates gradually until the thyristor

Power Transmission and Distribution, Fig. 14 Low-voltage frequency converter

is fully switched on, and the motor works on the mechanical characteristics under rated voltage to achieve smooth start. The starting process ends when the motor reaches the rated speed, and the soft starter automatically replaces the thyristor with a bypass contactor to provide the rated voltage for the normal operation of the motor. Figure 15 shows the typical low-voltage soft starter.

Umbilical

Umbilical is a combination of conductor (power conductor or signal conductor or both), optical fiber (single mode or multimode), insulation material, and outer sheath (steel or Kakra). The main parameters include rated voltage, rated current, outer diameter, minimum bending radius, air weight, sea water weight, safe working load, minimum breaking strength, etc. Figure 16 is a typical section of umbilical.

Power Transmission and Distribution, Fig. 16 Typical umbilical sectional view

Offshore Container

Offshore container is used to install the PDU, transformer, inverter, and other electrical devices or control system. It usually has IP56 protection

Power Transmission and Distribution, Fig. 17 Typical layout of container

level and is installed on the deck. The transformer and inverter generate mass of heat when in operation so it's very important for the container to cool down its internal temperature. Figure 17 shows typical internal layout of the container.

Definition

Preliminary design of a submersible is a stage of the design of a submersible. The process of the design of a submersible may be referred to in chronological order as the (1) pre-design, (2) design, and (3) post-design, and then the design process is composed of three design phases: (1) basic design, (2) contract design, and (3) detail design. The basic design consists of concept design and preliminary design stages, and preliminary design is the second stage of basic design. Starting with baseline data provided by the selected concept design(s), preliminary design refines and firms up the significant characteristics of systems, constraint, and relative cost estimates. Consequently, it provides a precise definition of the mission system and assurance that the design goal can be attained.

Scientific Fundamentals

Introduction to the Design Stage

As noted, the design process is composed of three phases called as basic design, contract design, and detailed design shown in Fig. 1. In this stage, the levels of labor, preparation time, and costs associated with each phase increase exponentially as the process progresses. Design creativity and flexibility are essentially limited to the basic design phase – the mission system, including its submersible system, being well defined at the beginning of contract design.

The design process, at this point, is discussed from the perspective of the mission system. As has been seen, this system is composed of (I) systems which may be labeled as new construction or existing systems. Design efforts focus on the total or “from scratch” design of new construction systems and on the selection of suitable existing systems and their alteration, if required, to convert them to (I) systems. The submersible, herein, is considered to be a new-construction (I) system (Allmendinger 1990).

The basic design is the primary design phase concerned with how best to accomplish what the

potential user/owner of the mission system wants to do underwater as set forth by his mission requirements. Basic design, as considered herein, is composed of the concept design and preliminary design. Concept design develops two or more design alternatives from which design is selected in accordance with specified criteria. Preliminary design advances the selected alternative’s development to the point of entry into the contract design stage. Basic design proceeds, in general, as discussed above, its process is discussed further in the next section.

Contract design requires yet further refinement of design and additional detail. It yields contract plans and specifications necessary for interested parties to bid on the construction of new (I) systems or the alteration of existing (I) systems. It also provides contractual documents for the construction and alteration work. Specifications delineate quality standards of material and workmanship as well as setting forth performance expectations for the (I) systems and their subsystem. They also describe tests and trails which must be performed successfully before acceptance of the systems.

Detailed design is the final phase of the design process and entails the development of detailed working plans from which the (I) systems are constructed or altered. In one sense, it is not a design phase since all the creative design effort is made in preceding phase, the design being unequivocally defined prior to entering this phase. It does, however, require the greatest amount of work of all the phases and is often undertaken by entities building or altering the system (Allmendinger 1990).

Missions in Basic Design Phase

As discussed above, the basic design phase leads the process of design, and the missions of this stage, in general, involves (Allmendinger 1990):

1. Development of performance requirements or (I) system capabilities, from the mission requirements.
2. Determination of the principal characteristics of the (I) systems required to achieve these

Preliminary Design, Fig. 1 Design and associated processes (Allmendinger 1990)

- capabilities, which enable new construction systems to be designed and existing systems to be selected and altered if necessary.
3. Estimation of capital and operating costs of (I) systems.
 4. Identification of one or a few mission systems from among a series of alternatives which optimally meet performance requirements to the extent possible considering design constraints acting.
 5. Refining and firming-up characteristics and cost estimates of the (I) systems composing the optimum concept design(s).

The concept design stage of basic design is concerned with the first four of these functions – function four, herein, is based on cost-effectiveness as the optimization criterion. The preliminary design stage of this phase is concerned with the fifth function.

Concept design, diagrammed in Fig. 2, is the first attempt to translate all the user/owner's mission requirements into performance requirements and characteristics of the (I) systems composing the mission system. It is often viewed as consisting of feasibility studies and completion of the optimum conceptual design (s) once they are identified by these studies. Feasibility studies are concerned with the development of those performance requirements and associated system characteristics which have significant impact on the cost-effectiveness optimization process. Completion of the optimum design(s) involves developing other major performance requirements and characteristics those which are essential in defining (I) systems but which do not have a significant impact on the optimization process (Allmendinger 1990).

Feasibility studies create an orderly series of mission system alternatives, all of which meet the mission requirements and are technically feasible, and select one or a few of these alternatives as the conceptual design(s) to be carried on into preliminary design. These alternatives are shown in Fig. 2 as $MS_1, MS_2, \dots, MS_i$, where "i" can be any small to large number depending on the simplicity/complexity of the mission and

optimization techniques used. As indicated in the figure, each alternative is composed of a unique combination of (I) systems. Each (I) system, in turn, has unique capabilities, characteristics required to achieve these capabilities, and costs associated with providing these characteristics. Certain unique (I) systems may appear in more than one combination, but individual combinations are not duplicated in other alternatives. Mission system alternatives may be generated by (1) varying performance requirements with the cascading effect of varying (I) systems' capabilities, characteristics, and costs and (2) varying (I) systems' capabilities, characteristics, and costs in ways each of which meets a specific set of performance requirements. Alternatives generated in this manner contain information necessary to conduct the search for the optimum, cost-effective mission system(s).

Combinations of (I) systems forming mission system alternatives may vary in number, type/capabilities, and status. These features are related to functions required to accomplish mission tasks, the time frame for completing these tasks, if critical, and economic considerations. A mission profile, derived from mission requirements, is useful in providing functions and time-frame information – its usefulness increasing as the complexity of the mission increases. This profile is a chronological listing of all events occurring from the mission's beginning to end and including time-frame data where necessary.

The other "exit line" from the optimization process, as indicated in Fig. 2, leads to the optimum mission system(s) identified by this process in a manner suggested by the cost-effectiveness equation. The concept design(s) of the selected mission system(s) can now be completed by developing the primary characteristics of the (I) systems not considered in the feasibility studies. The identification of more than one optimum concept design means that the "optimization curve" is reasonably flat over a limited range of alternatives – that there is little to choose between them. In this instance, the user/owner may select one of them based on subtleties not heretofore considered or more than one may be carried

Preliminary Design, Fig. 2 Basic design of mission system (Allmendinger 1990)

forward into preliminary design. The mission system(s) carried forward should have associated performance requirements firming up and provide baseline (I) system characteristics which are further developed and during the preliminary design stage.

Preliminary design, as noted, is the second stage of basic design and is concerned with this phase's fifth function. Starting with baseline data provided by the selected concept design(s), preliminary design refines and firms up the major

characteristics of systems, constraint, and relative cost estimates. Consequently, it provides a precise definition of the mission system and assurance that the design goal can be attained.

Figure 1 shows a "feedback line" from preliminary design to the mission requirements, indicating that refinements in the design may reveal technical feasibility reasons for altering performance and, in summary, mission requirements that were overlooked in concept design. These discoveries should be few in number and minor

in their effect on the requirements. A significant discovery of this nature would, most likely, raise doubts about the validity of selected concept design(s) and be the cause for repeating the concept design stage or terminating the design altogether (Allmendinger 1990).

Regarding basic design, the major systems comprising submersible are summarized in the following outline (Allmendinger 1990):

1. Hull Structure System: (a) Structure System, (b) Special System.
2. Propulsion Plant System: (a) Energy Generating System, (b) Propulsion System, (c) Special Purpose System.
3. Electrical Plant System: (a) Electrical Power Generation System, (b) Power Distribution System, (c) Lighting System, (d) Special Purpose System.
4. Command and Surveillance System: (a) Command and Control System, (b) Navigation System, (c) Communication System, (d) Surveillance System, (e) Special Purpose System.
5. Auxiliary System: (a) Human System, (b) Life Support System, (c) Air, Gas and Miscellaneous Fluids System, (d) Submersible Control System, (e) Mechanical Handling System, (f) Special Purpose System.
6. Outfit and Furnishings System: (a) Fittings System, (b) Hull Compartmentation System, (c) Preservatives and Covering System, (d) Furnishings, (e) Special Purpose System.
7. Armament System (This system applies only to submersibles having offensive/defensive military missions requiring the launching of weapons). The above introduction mostly came from Allmendinger (1990) which was based heavily on Busby (1976). More detailed introduction from Busby (1990) and Funnel (1999).

The Process of the Preliminary Design

This section discusses the process of the preliminary with the well-known design spiral which serves as a basis for a brief discussion of the entire design process. The design spiral is shown in Fig. 3.

The design spiral – The iterative nature of the overall design process may be modeled by the design spiral shown in Fig. 3. The spiral consists of spokes and loops. The spokes represent design considerations including performance requirements, submersible characteristics, and cost estimates; submersible characteristics are embodied in its arrangement, geometry, six systems groups, and summaries of energy requirements and weight/displacement centers. The loops indicate design iterations with the design's refinement increasing as the loops spiral inward. Outer loop procedures use empirical formulations and estimates based on similar design data, whereas middle and inner loop procedures are based on the progressively more detailed development of the design considerations utilizing increasingly precise formulations. The intersection of spokes and loops form "points" which are identified alphanumerically. Thus, for example, 3B is a point in the spiral at which the geometric characteristics of the submersible are being considered in the second iteration in a more detailed manner than they were initially at point 3A. At 3B, adjustments are made as the result of both the more detailed consideration of the geometric characteristics required and the impact on geometric of interrelated design considerations for which data were generated at points in spiral preceding 3B. Adjustments are made at other points in the spiral for the same reasons. For the design to converge to a satisfactory solution of the design problem, these adjustments must become progressively similar with each succeeding loop through concept, preliminary, and contract design. This fact is demonstrated in the spiral by the decreased spacing between loops as they spiral inward. Convergence is illustrated by the innermost loop becoming a circle, indicating that all design considerations are fully developed and required no further adjustments. At this point in the spiral, detailed design can begin (Allmendinger 1990).

Preliminary design is arbitrarily limited to loops C, D, and E. Note in the Fig. 3 that loops D and E are relatively close together, indicating that only very small adjustments in design

Preliminary Design, Fig. 3 Design spiral (Allmendinger 1990)

considerations are being made at this point. Should preliminary design's more detailed procedures and exact formulations reveal the need for relatively large adjustments to be made in one or more of the considerations, the validity of the selected concept design alternative may well be questioned. The end result of preliminary design is a well-defined submersible system which meets performance requirements and for which a firm cost estimate exists. As indicated on the spiral, completion of this phase of design marks the beginning of contract design.

The C, D, and E loops – The preliminary design procedures of these loops progressively refine all aspects of the submersible's design, including those aspects not considered in the concept design phase. Only small adjustments, if any, are required at the spiral's point at the end of the E loop. Some general comments on these points follow.

- (1) C, D, E Performance Requirements: Review these requirements in light of the design's more detailed development. C and D loop

procedures may reveal that it is still necessary or desirable to make small changes in some of these requirements. There should be no changes in them as the result of E loop procedures or, in words, they should be fixed at entry into the contract design phase.

- (2) and (3) C, D, E Arrangement and Geometry Displacement: Obtain a detailed view of the submersible with the location of systems being essentially fixed so that the systems can function properly, routine inspection and maintenance can be made with relative ease, there are no conflicts in space requirements, and the design condition criteria of adequate stability and zero trim are met. These procedures require detailed inboard/outboard profiles and cross-section views to be drawn. A line drawing may also be drawn depicting the envelope's geometry; this drawing is necessary to obtain accurate data required for hydrostatic and hydrodynamic calculations.
- (4–9) C, D, E Systems Groups: Develop these systems in sufficient detail to provide the assurance that, both individually and collectively, they will satisfy all performance requirements and very close estimates of sizing and cost data. Direct calculations and preliminary drawings, as contrasted with working drawings, are used extensively. Procedures, for example, may involve the construction and testing of structural and appended envelope models to verify data derived from theoretical strength and hydrodynamic formulations.
- (10) C, D, E Energy Summary-Energy Storage Systems: Make progressive refinements of electrical power-energy profile and pneumatic storage system based on increasingly precise C, D, E loop SWBS data. Electrical and pneumatic storage systems should be very accurately defined at point 10E.
- (11) C, D, E Weight-Displacement-Center Summary: Complete this summary in more detail and investigate stability and trim in design and other operating condition as well as in the emergency ascent condition. These procedures will require a breakdown of SWBS systems into their components.

Procedures at 11C and, to a lesser extent, at Point 11D usually indicate that some adjustments in arrangement or system details or both are necessary to attain design condition criteria of neutral buoyancy, adequate stability, and zero trim. They may also indicate that adjustments in envelop geometry and systems influenced by this characteristics are necessary to obtain adequate surface stability. These adjustments, if any, are to be made, should be relatively small on entry into the contract design phase.

- (12) C, D, E Cost Estimate Summary: Summarize the progressively refined first and annual operating cost estimates obtained in these loops. A close estimate of the submersible's operating cost per year should be in hand at the beginning of contract design (Allmendinger 1990).

Key Applications

Preliminary design is a significant step of the design of submersibles. Here we introduce the autonomous underwater vehicle (AUV) and remotely operated vehicle (ROV).

Autonomous Underwater Vehicles (AUV)

The applications of the underwater vehicle have shown a dramatic increase in recent years, such as, mines clearing operation, feature tracking, cable or pipeline tracking, and deep ocean exploration. To satisfy different applications, different kinds of development of autonomous underwater vehicles or their systems appear. Martz (2008) applied multidisciplinary design optimization method to the preliminary design of an AUV. Allotta et al. (2011) developed an innovative AUV called Tifone and finished the preliminary design, as is shown in Fig. 4. Salleh et al. (2013) performed preliminary design of AUV with higher resolution underwater camera for marine exploration.

Remotely Operated Vehicles (ROV)

In the design stage of ROV, in order to make it a free-flying vehicle, floatation is added to

Preliminary Design,

Fig. 4 Preliminary layout of Propeller and Thrusters on Tifone Vehicles (Allotta et al. 2011)

**Preliminary Design,**

Fig. 5 Vehicle's righting moment (Christ and Wernli 2014)

neutralize vehicle buoyancy and achieve mobility in Fig. 5 (Christ and Wernli 2014). Thus, one of the key points in preliminary design of an ROV is to realize the performance requirements and, at the same time, to keep its stability. Bowen et al. (2004) finished the preliminary design of a novel light-tethered hybrid ROV for global science in extreme environments. Govinda et al. (2014) studied modelling, design and robust Control of a ROV in preliminary design stage.

Probabilistic Aspects for Ice Loads on Ships

Wei Chai

Departments of Naval Architecture, Ocean and Structural Engineering, School of Transportation, Wuhan University of Technology, Wuhan, China
Department of Marine Technology, Norwegian University of Science and Technology, Trondheim, Norway

Introduction

For ships in the Arctic, ice loads caused by ship and ice interaction represent the dominant load. Ice loads on ship hull is random by nature as other environmental loads. The knowledge of ice loads can promote design and operation of ice-capable vessels in Arctic regions. However, due to the complexity of ship and ice interaction process, studies with respect to the ice loads are limited and still under development. Ice loads on ship hull can be calculated by empirical formula and numerical simulation and collected by laboratory experiments and full-scale field measurements. Among these methods, full-scale field measurements are the most effective way to study the properties of ice loads (Ehlers et al. 2015). In this entry, the randomness of ice loads and the reasons that cause the randomness of ice-induced loads are introduced. Previous studies for probabilistic descriptions and analysis of the full-scale measured ice loads on ship hull are summarized in this work. The challenges and future works for studying the stochastic properties of ice loads on ship hull are also described in this entry.

Randomness of Ice Loads to Ships

Ice loads are caused by the ship and ice interaction process, which depends on the ice conditions, the geometry of ship hull, and the relative velocity between the vessel and the ice features. Generally, for first-year ice, the ship and ice interaction process is initialized by a localized crushing of

the free ice edge, and then the contact area and crushing forces increase as the ship advances and penetrates the ice features. The ice eventually deflects, and the bending stress promotes a flexural failure at a certain breaking distance from the crushing region (Jordaan 2001). The interaction process is illustrated in Fig. 1, and some other kinds of failure mode (e.g., creep, cracking, bucking) may occur separately or in combination during the interaction process. Even though the interaction between ice features and ship hull is governed by deterministic laws of mechanics, ice loads on ship hull are random by nature (e.g.,

Fig. 2). The stochastic nature ice loads have has also been validated by various full-scale field measurement campaigns, which are listed in Ehlers et al. (2015) and Suominen (2018).

During the full-scale measurement voyages in ice regions, strain sensors are instrumented to measure the (local) ice loads on ship hull. It is seen in Fig. 2 that the time series of measured ice loads on a frame looks like a sequence of impulses with sharp peaks, which indicate that during the ship and ice interaction process, the accumulated crushing force is high enough to initiate bending failure of the ice feature. Such impulses are

Probabilistic Aspects for Ice Loads on Ships, Fig. 1 An illustration of ship and (first-year) ice interaction process (Riska 2010)

Probabilistic Aspects for Ice Loads on Ships, Fig. 2 Stochastic nature of the ice loads measured on a frame (Lensu 2002)

repeated as the ice-breaking process continues and the peak values of the ice loads are referred to as the ice load peaks.

There are mainly two categories of sources causing the randomness of ice-induced loads. One is the variation of the ice conditions in the Arctic regions, which includes physical ice properties (such as ice types, thickness, density, porosity, floe size, etc.) and ice mechanical properties (e.g., flexural, tensile, shear, uni- and multiaxial compression strength, and so on). The other is related to the complex ship and ice interaction process in association with different ice failure mechanisms and randomness of flaw in ice features. In addition, ship operations and movements in different ice conditions also affect the ice-breaking process and the values of ice loads.

Probabilistic Analysis of Ice Loads to Ships

For stochastic processes, probabilistic models and methods should be applied to describe their properties. Within the scope of probability theory, standard methods, such as the statistical parameters (e.g., the mean value, standard deviation, skewness, kurtosis), correlation functions, power spectrum, statistical distributions, extreme value statistics, etc., can be applied to analyze the time series of the random load process (Ochi 1990). In this entry, previous studies on the statistical distributions of the measured ice loads, extreme value statistics, and fatigue damage evaluation based on the collected ice load peaks are summarized.

Probabilistic Models of Ice Loads

In general, the full-scale measurements can be classified as long term and short term. Long-term measurements are usually taken over several winter seasons, and they have been performed only in the Baltic Sea and the Antarctic sea (Kujala 1994). Basically, most of the full-scale measurements are based on the short-term measurements in which the time periods are hours and minutes. Ice load peaks collected by short-term measurements are widely used for probabilistic analysis.

Kheisin and Popov (1973) were the pioneers in introducing the probability theory to study the ice loads on ship hull. In their study, it was found that the number of ice load events in the ship bow region is distributed according to the Poisson law and the measured ice load peaks were found to follow an exponential distribution. Subsequently, there have been plenty of studies on probabilistic models of the measured ice loads on ship hull. Kujala and his colleagues suggested that the Weibull probability distribution or the exponential distribution or lognormal distribution would give the best fit to the ice loads data collected in the Baltic Sea (Kujala 1994; Suominen 2018). Figure 3 presents an example of measured ice load peaks fitted by different probabilistic models. In addition, Jordaan et al. (1993) applied the event-maximum method and found that the tails of ice loads collected in the North Chukchi sea can be fitted as an exponential distribution by using probability paper method.

However, from the full-scale measurements of ice loads collected onboard KV Svalbard in the sea area of Spitsbergen in the year 2007, Suyuthi et al. (2013b) mentioned that some sets of (short-term) ice load peaks cannot be well modeled by the traditional statistical models, such as the lognormal and the exponential distribution. Later, they proposed a generalized probabilistic model, i.e., a three-parameter exponential distribution to provide a better description of these collected

Probabilistic Aspects for Ice Loads on Ships, Fig. 3 Different probabilistic models for fitting the measured ice load peaks (Suominen 2018)

data sets (Suyuthi et al. 2014). As a result, the three-parameter exponential distribution can serve as an effective supplement to the traditional statistical models for describing the measured ice load peaks.

Extreme Value Statistics

The extreme value statistics of ice loads are directly related to the reliability of the ice-capable vessels since the ultimate limit states (ULS) are generally based on extreme load effects. Assume that the stochastic process $X(t)$ represents the ice load peaks over a time interval $[0, T]$. The values $X_1, \dots, X_N$, which were derived from the observed process, are allocated to the discrete times $t_1, \dots, t_N$ in the time interval $[0, T]$. The extreme value among the N outcomes of the stochastic process $X(t)$ is defined as $M_N = \max \{X_1, \dots, X_N\}$, and the extreme value distribution for large values of η is expressed as:

$$\begin{aligned} P(\eta) &= \text{Prob}(M_N \leq \eta) \\ &= \text{Prob}(X_1 \leq \eta, \dots, X_N \leq \eta) \end{aligned} \quad (1)$$

Former studies of extreme loads prediction are mainly based on the classic extreme value theory, which includes the peak amplitude approach (Ralph and Jordaan 2013) and the asymptotic method (Lensu 2002). For the peak amplitude approach, it is assumed that all the N collected ice load peaks are independent and identically distributed with common distribution, $F_X(x)$, such as the Weibull, exponential, and lognormal distributions, described in section “Probabilistic Models of Ice Loads.” Then, the extreme value distribution is given in the form of the power of encountered number of ice loads events as Eq. 2. The relationship between the distribution of ice load peak $F_X(x)$ and the extreme value distribution $P(\eta)$ is illustrated in Fig. 4.

$$\begin{aligned} P(\eta) &= \text{Prob}(X_1 \leq \eta, \dots, X_N \leq \eta) \\ &= \prod_{i=1}^N \text{Prob}(X_i \leq \eta) = [F_X(\eta)]^N \end{aligned} \quad (2)$$

In the asymptotic method, a proper number of time windows with equal duration are

Probabilistic Aspects for Ice Loads on Ships, Fig. 4 Illustration of the relationship between the initial distribution (i.e., distribution of ice load peaks) and the extreme value distribution

selected to divide the measured time series into a corresponding number, K , of intervals. The maxima value in each interval is identified. Then, based on the collected maxima data, the type I asymptotic extreme value distribution, i.e., the Gumbel distribution, is applied to estimate the extreme distribution:

$$P(\eta) = G_Y(\eta) \quad (3)$$

where Y represents the process of maxima values in the K intervals and $G_Y(y)$ is the Gumbel distribution with the following expression:

$$G_Y(y) = \exp \left\{ -\exp \left[-\left(\frac{y - \beta}{\alpha} \right) \right] \right\} \quad (4)$$

where α and β are the parameters for the Gumbel distribution and they can be estimated by ordinary fitting of the empirical cumulative distribution, such as the least-square fitting in a probability paper and the method of moment, etc.

This method is also known as the Gumbel method. In this method, for small level of exceedance probability λ , the corresponding extreme value is given as:

$$\eta = G_Y^{-1}(1 - \lambda/K) \quad (5)$$

In addition to the abovementioned two methods based on the parametric distribution functions, there is another method, named as the ACER (average conditional exceedance rate) method, which can be applied to estimate the extreme distribution of the collected ice load peaks. The ACER method is based on a sequence of nonparametric distribution function and estimates the extreme value distribution by constructing different orders of the ACER functions, which are available for both the stationary and non-stationary data sets. The principle and development of the ACER functions are described in Næss and Gaidai (2009).

In this method, with the time series of the measured ice load peaks, the extreme value can be estimated in the following manner:

$$P(\eta) \approx P_k(\eta) \approx \exp(-(N - k + 1) \cdot \hat{\varepsilon}_k(\eta)) \quad (6)$$

where k is the order of the ACER function and P_k represents the approximation of the extreme value distribution based on the k th order ACER function. $\hat{\varepsilon}_k(\cdot)$ is the empirical ACER function of order k , which can be obtained by applying the existed time series.

In order to predict the extreme value distribution in the tail region, an extrapolation scheme is applied. This extrapolation technique is based on the observations that for ships and marine structures being considered, the mean upcrossing rate and the ACER functions are in general highly regular in the tail region. The empirical ACER function is assumed to be in the form of:

$$\hat{\varepsilon}_k(\eta) \approx q_k \exp\{-a_k(\eta - b_k)^{c_k}\}, \quad \eta \geq \eta_0 \quad (7)$$

where a_k , b_k , c_k , and q_k are suitable constants, which are dependent on the order k .

Generally, under the aforementioned assumptions for the tail region of the ACER functions, plotting $\log|\log(\hat{\varepsilon}_k(\eta)/q_k)|$ versus $\log(\eta - b_k)$ would give an almost perfect linear tail behavior. In addition to this method, a more robust Levenberg-Marquardt least-squares optimization method can be used to determine the optimal values for a_k , b_k , c_k , and q_k . Details of this method can refer to Naess and Moan (2012) and Chai et al. (2016). An example of extreme value estimation for the collected ice load peaks is presented in Fig. 5. Moreover, the performance of the abovementioned three methods applied for estimation of the extreme values of ice load peaks has been systematically reported in Chai et al. (2018a).

Probabilistic Aspects for Ice Loads on Ships,

Fig. 5 An example of extreme estimation for the collected ice load peaks based on the ACER₁ function

Fatigue Damage Evaluation

In addition to the extreme ice loads statistics, fatigue damage caused by cycle ice loading is also an important issue for Arctic ships navigating in severe ice regions. Generally, fatigue damage evaluation is based on the S-N data in association with the Palmgren-Miner law of damage accumulation. For the ice load-induced fatigue damage, when the time series of ice-induced stress ranges are available, fatigue damage of ship hull can be directly estimated by summing the fatigue damages of all stress cycles according to the linear Palmgren-Miner cumulative rule or estimated by probabilistic manners when the distribution of stress ranges is known. Current studies for fatigue damage of ship hull due to ice loads actions are limited and only for short-term collected ice load peaks and the associated ice-induced stress ranges (Chai et al. 2018b; Suyuthi et al. 2013a). Assessment of fatigue damage for long-term measurements remains undeveloped.

Future Work

The abovementioned former studies are focus on the short-term measured ice load peaks. The methods mentioned in this entry can also be extended for long-term studies when relevant long-term measured data is available. Such studies for extreme value analysis of the ice loads and fatigue damage evaluation are directly related to the ultimate limit states and fatigue limit states of the Arctic ship during its service life.

In addition, ice thickness is assumed to be the most representative parameter for the severity of the ice conditions. The ice thickness during the full-scale measurement voyage can be regarded as a random process with respect to time space. Due to the stochastic nature of ice loads and ice thickness, it is a challenge to establish a link between the prevailing ice conditions and ice-induced loads. This study would be achieved when the relevant long-term measured data is available.

Furthermore, for current rule-based design method for Arctic ships, the reliability-based design method with considerations of the

randomness and uncertainties of the ice condition and ice loads could be an effective supplement.

Definition

Profiling float is also called “Autonomous Lagrangian circulation explorer (ALCE)” or “Self-sustaining profiling automation circulation detector (SPACD).” It is a measurement instrument which can freely drift in the ocean, and it uses the Lagrangian circulation method to automatically measure seawater temperature, electrical conductivity (salinity), and pressure from the sea surface to a certain depth and tracks the drift trajectory to obtain the velocity and direction of the current (Xu 2002).

Scientific Fundamentals

Working Principle

There are usually three ways in which objects can ascent and descent in water. One is to change the volume of the object without changing the weight; if the volume changed, the buoyancy will be changed; the other is to change the weight while keeping the volume constant, and then the net buoyancy is changed; the third is to increase or decrease the applied external force (Xu 2002; Yu et al. 2001).

Early neutral floats changed the net buoyancy by changing their weight to achieve the motion ups and downs, so the volume were relatively large and cumbersome, and repeated measurements could not be performed. After a period of development, a method of changing the volume was used in the design of neutrally buoyant float. The neutrally buoyant floats periodically change their buoyancy by pumping the hydraulic fluid from an internal reservoir to an external bladder, thereby increasing float volume and buoyancy, so repeated measurements can be achieved, and the volume of the float was reduced a lot at the same time.

History of Profiling Float

The prototype of profiling float is a measurement instrument made by using Euler and Lagrange method to detect the sea surface or deep currents. Profiling floats were developed on the basis of neutral buoyant floats and integrated sensor technology, satellite positioning technology, and communication technology.

In the summer of 1955, John Swallow made his first visit to the National Institute of Oceanography to discuss with oceanographers the possibility of making direct measurements of the vertical profile of currents in the deep ocean (Gould 2005). Swallow is the pioneer to develop the neutrally buoyant float.

The first floats were constructed at the beginning of 1955 in the National Institute of Oceanography (NIO). At that time, materials and money were in short supply; the standard tubing had too great a wall thickness, so they put the tubes in a bath of caustic soda to thin the wall. Only

6 months after construction started, the first floats were deployed in June 1955.

The floats weighed around 10 kg in air but had to be weighed in water in order that they could be ballasted to stabilize at their target depth. This was done by suspending each float from a simple chemical balance mounted above a tube of salt solution (close to a salinity of 35 and mixed by repeatedly lowering a bucket down the tube and hauling it up again to prevent stratification) in the stairwell of the NIO. The density of the saline solution was measured using high school physics techniques (specific gravity bottles). The floats needed only 38 g of negative buoyancy to stabilize at 1000 m, so great care was needed with the weighing and density calculations and to eliminate trapped air bubbles. Floats were used by NIO scientists in Labrador (See, Fig. 1).

Though only two worked satisfactorily in the six floats, the method had been demonstrated, and the results were detailed enough to show evidence of tidal variations (Swallow 1955).

However, the concept of neutrally buoyant float had also been developed simultaneously and independently on the other side of the Atlantic. Stommel had also put forward to directly measure the deep currents by using the subsurface neutrally buoyant floats (Stommel 1955). He supposed that deep currents should be tracked through the Sound Fixing and Ranging (SOFAR) channel by the floats creating regular explosions.

However, the discovery of an energetic ocean mesoscale exposed the limitations of ship-tracked floats. If the mean ocean circulation were to be revealed, so continuous observations over months would be needed.

The problem was addressed by Rossby and Webb (1970); the floats could be tracked by sound transmissions through the SOFAR channel. Then hydrophones could be used to monitor the floats. The first two SOFAR floats (Fig. 2) were deployed in the Sargasso Sea in 1968 and showed that reception of signals was possible at ranges

Profiling Float, Fig. 1 John Swallow (left) and Gordom Volkmann on R. V. Erika Dan in 1962. The float shown here is essentially identical to floats deployed between 1957 and 1970 and using 10 kHz magnetostrictive nickel scroll transducers (Gould 2005)

Profiling Float, Fig. 2 Prototype SOFAR float (Gould 2005)

of up to 1000 km and that float positions could be determined with an accuracy of the order of 3–5 km and with a life time of 9–12 months. In 1969, a float operating at 380 Hz was tracked for 4 months and confirmed the robustness of the technique. Each float weighed around 430 kg and was over 5 m long. The floats also had a 10 kHz, short-range navigation system to allow their location and subsequent recovery by a ship (Rossby and Webb 1971).

The restriction of SOFAR floats at that time to depths near the sound channel axis (due to depth restrictions on the pressure cases) meant that it was not possible to use these floats to explore the vertical structure of currents over most of the water column (Swallow 1977). Thereby, a ship-based system using transponding floats made it possible by improved transducers, and microelectronics was developed by John Swallow and his coworkers (Swallow et al. 1974). The system allowed up to 18 floats to be tracked simultaneously. This ability to interrogate from a wide range of depths allowed tracking of floats at all depths and the achievement of ranges of up to 70 km. The SOFAR floats enabled day-to-day objective mapping of the ocean meso-scale over an area 400 km² and revealed the long-term propagation of these features (Freeland et al. 1975; Freeland and Gould 1976).

From the mid-1970s, acoustically tracked floats were used extensively to further explore the ocean's mesoscale structure and variability.

In the mid-1980s, there was a considerable interest in the potential for the disposal of radioactive waste either below or on the sea bed. Acoustically tracked floats were ideal for investigating the ocean circulation around potential disposal sites (Gould 2005).

With the increasing of the investigation depth, the pressure cases of the aluminum tube could not meet the needs. Then floats using glass spheres as pressure cases were developed both in France and in the USA. The floats designed by Webb Research Corporation (WRC) using four glass spheres and transmitting at 260 Hz could reach the depths close to 3000 m with a lifetime of about 4 years (Rees and Gmitrowicz 1989) (Fig. 3).

Profiling Float, Fig. 3 Deep SOFAR float using glass spheres. The uppermost sphere provides buoyancy, the middle two hold batteries, and bottom sphere contains electronics. The float is seen in a deployment cradle that was opened hydraulically when the float was below the sea surface (Gould 2005)

Due to the SOFAR tracking system needed to place the bulky and heavy sound sources on moorings, thus the usage of long-range floats was restricted. For this reason, the smaller and cheaper RAFOS floats were developed by Tom Rossby and his group (Rossby et al. 1986, 1993) to record the signal arrivals from an array of moored sources and transmit the data back to satellites when they surface at the end of their mission.

The applications of various types of floats during the 1970s, 1980s, and 1990s on the scientific investigation were extensive and significantly improved our understanding of the oceanic eddy fields (Webb et al. 1970; Gascard 1973; Rossby et al. 1994; D'Asaro et al. 1996).

Due to the measurement could not be done repeatedly by means of dropping a ballast weight,

the Autonomous Lagrangian circulation explorer (ALACE) was developed (Davis et al. 1992). It is a novel system which can be tracked globally. ALACE was subsurface float that cycles vertically from a depth where it was neutrally buoyant to the surface where it was located by, and relays data to, System Argos satellites (Davis et al. 1992). This type of float periodically changes their buoyancy by pumping hydraulic oil from an internal reservoir to an external bladder, thereby increasing float volume and buoyancy.

Because of positioning and data relay are accomplished by satellites, ALACEs are autonomous of acoustic tracking networks and are suitable for global deployment. Schematic of ALACE is shown in Fig. 4.

After that, the oil bladder regulation device was widely used in the design of profiling float.

As the small, low-power, autonomous CTD sensors with good long-term stability were developed by Falmouth Scientific Instruments and Sea-Bird Electronics, the full temperature and

Profiling Float,

Fig. 4 Schematic of an ALACE. To ascend, the hydraulic pump moves oil from internal reservoir to external bladder. To descend, the latching valve is opened allowing oil to flow back into internal reservoir. Antenna shown to right is mounted on the top hemispherical endcap (Davis et al. 1992)

conductivity profiles were developed, and ALACE floats evolved to P-ALACE floats (Davis et al. 2001).

The research of profiling floats began at the end of the Ninth Five-Year Plan (1996–2000) in China. COPEX profiling float was successfully developed by the National Ocean Technology Center of China in 2003. Another type of profiling float HM2000 was developed by 710 Research Institute of China Shipbuilding Industry Corporation (CSIC) in 2015.

Although the development of profiling floats started relatively late in China, the Beidou satellite navigation and positioning system developed in China has the ability to determine the geographical location of users. In and around China, two-way brief digital message communication can be realized between the users, the user and the central control system in the Beidou user machine system. The user terminal has two-way digital message communication capabilities and has been successfully applied in profiling floats (Zhang et al. 2009; Wu et al. 2013).

Due to the observation-based studies that demonstrated the warming of the deep ocean below 2000 m has significantly contributed to the mean sea level rise (Purkey and Johnson 2010; von Schuckmann et al. 2014), a strong requirement was proposed from the ocean and climate research community to expand the Argo coverage into the deep ocean below 2000 m. This was an essential element of the global ocean observing system envisioned by the OceanObs'09 conference (Garzoli et al. 2010; Church et al. 2011). Then four types of deep-ocean profiling float were developed, Deep Arvor, Deep NINJA, Deep APEX, and Deep SOLO. Deep Arvor and Deep NINJA can reach the depth of 4000 m; Deep APEX and Deep SOLO can reach a greater depth of 6000 m (Zilberman and Maze 2015; Reste et al. 2016). The deep-ocean profiling floats were shown in Fig. 5.

Technical Challenge

From the development process of profiling float, we can see that the industrial foundation largely determined the performance. The buoyancy

regulation devices evolved from changing weight to changing volume; pressure hull evolved from aluminum housings to alloy hulls to glass spheres, etc., which can stand greater water pressure and explore deeper. However, to design a profiling float with superior overall performance is a systematic engineering.

1. Energy Efficiency

The buoyancy regulation system is the basis for achieving ups and downs of the profiling floats, and it determines the performance of the float largely. The power consumption of the motor accounts for about 60% of the total power consumption of the measurement process (Reste et al. 2016). The energy efficiency is not only related to the motor, hydraulic pump, but also related to the control algorithm, the transmission speed of the communication and positioning system, and other factors.

2. Diving Depth

The increased diving depth will inevitably lead to an increased difficulty of design. An increased design depth results in lower pump efficiency, higher motor power consumption, and higher requirements to the pressure material. Weight is also an important indicator for evaluating the performance of profiling floats. Lightweight profiling floats facilitate handling and deployment. The weight control is also a systematic project that involves every design element and component of the floats. Therefore, the pursuit of better performance will inevitably increase the cost.

3. System Reliability

There are many causes of failure of the profiling floats, such as failure of the communication and positioning function, sensor failure, battery leakage, hydraulic oil leakage, failure of the pressure hull under special conditions, and so on.

Reliable satellite transmission is critical to achieving the scientific goal of measuring subsurface currents. Surface drift must be accurately measured so that measurements of the much slower subsurface motions are not contaminated. Positions are not obtained exactly at

the surfacing and descent times; therefore, it is necessary to extrapolate the observed positions to these times. Because this requires obtaining as many positions as possible, an important design objective for profiling float is to obtain

good surface following so that the antenna is rarely submerged.
Another difficult problem is to avoid the loss of prime in the high-pressure pump caused by air bubbles in the hydraulic fluid.

Profiling Float, Fig. 6 Park & Profile Mission Operation (http://www.argo.ucsd.edu/How_Argo_floats.html)

P

Profiling Float, Fig. 7 Measurement process of float equipped with an ice probe sensor (<http://www.argo.org.cn/index.php?c=index&catid=17&contentid=453&f=show&m=content>)

The system reliability is closely related to the design and development process. Therefore, the reliability runs through the entire process of the floats.

Key Applications in the Argo Plan

Argo is a global array of 3800 free-drifting profiling floats that measures the temperature and salinity of the upper 2000 m of the ocean. This allows, for the first time, continuous monitoring of the temperature, salinity, and velocity of the upper ocean, with all data being relayed and made publicly available within hours after collection. The measurement process of regular Argo float and high-latitude ice exploration float was shown in Figs. 6 and 7, respectively.

The origins of Argo can be found in the 1990–1997 World Ocean Circulation Experiment (WOCE). WOCE is part of the World Climate Research Programme (WCRP) and set out to collect an unprecedented set of observations. WOCE needed to collect data on ocean currents at about 1000 m throughout the oceans.

Pure Loss of Stability

Min Gu, Jiang Lu, Shuxia Bu, Jilong Chu,
Ke Zeng and Tianhua Wang
China Ship Scientific Research Center (CSSRC),
Wuxi, China

Synonyms

[Loss of stability](#); [Ship loses restoring in waves](#)

Definition

Pure loss of stability was firstly named by Paulling as a kind of capsizing mode (1961) and afterward was under research and realization. Germany proposed pure loss of stability to be part of the stability criteria in the development of IMO in the second generation intact stability criteria. The case diagrammed in Fig. 1 shows a large wave approaching the ship from the stern, while the ship is underway with relatively high speed in following seas. If the celerity (speed) of the large wave is just slightly above the ship speed, the duration needed for the large wave to pass or overtake the ship may be long (“long” here means at least an order of magnitude greater than the natural roll period). Once the crest of the large wave is near the midship section of the ship, the righting lever may be significantly decreased. Further, because of the significant duration that this condition may exist, a large heel angle may develop, which could lead to capsize.

Pure Loss of Stability, Fig. 1 A possible scenario for the development of pure loss of stability (Belenky et al., 2011; SDC 3/WP.5/Annex 3, 2016)

Historical Development

The stability in waves often becomes larger at the trough and becomes smaller at the crest comparing with that in calm water (Paulling, 1961). Pure loss of stability was identified during the model experiments in San-Francisco Bay (Paulling et al., 1972, 1975), and considered as a static capsizing mode that ship loses static restoring in waves (Oakley et al., 1974). Many researchers focused on the method to calculate the GZ curve in regular and irregular waves (Kuo et al., 1986; Hamamoto & Nomoto, 1982). One method for calculating the restoring variation in waves was developed by using the strip method of heave and pitch motion instead of the static method (Umeda et al., 2005).

The restoring moment in irregular waves is considered a stochastic process (Dunwoody, 1989; Palmquist, 1994; Bulian & Francescutto, 2006). The Grim effective wave is used to

evaluate the probability of capsizing due to pure loss of stability in short-crested irregular stern-quartering waves (Umeda & Yamakoshi, 1993). The waves are assumed to be a narrow-banded stochastic process instead of the Grim effective wave (Vermeer, 1990). The concept of a “critical wave” is used to evaluate the probability of capsizing (Themelis & Spyrou, 2007). The effective wave approach combined with the up-crossing theory is used to produce a time-dependent probability of stability failure (Bulian et al., 2008). The application of the split-time method to pure loss of stability is discussed by Belenky et al. (2015).

Pure loss of stability is a nonlinear phenomenon involving a large amplitude roll motion, and Spyrou (Spyrou, 1997) suggested that the loss of stability could be related to periodic motion, accumulative broaching, and so on and it is still difficult to be predicted quantitatively. Hashimoto carried out experiments on pure loss of stability

in following seas with an initial heel moment induced by cargo shift (Hashimoto, 2009). Jiang Lu further confirmed capsizing due to pure loss of stability may not be reproduced in the simulation and experiment in following seas without initial heel moments (Lu et al., 2019).

Umeda firstly pointed out that pure loss of stability in stern quartering waves could not be really pure, and also the heeling moments induced by a centrifugal force due to ship maneuvering motions are the relevant external moments (Kubo et al., 2012). Umeda further argued the capsizing of the actual ship in stern quartering waves could be due to ship maneuvering motions of sway and yaw (Umeda et al., 2019). Jiang Lu further confirmed that the coupling force from the maneuvering sway and roll motions to roll motion is a key factor for pure loss of stability in stern quartering waves (Lu et al., 2020).

Key Numerical Method for Pure Loss of Stability

The 4-DOF mathematical model is expressed by the surge, heave, roll, and pitch for pure loss of stability in following waves in the reference (Lu et al., 2019). The 6-DOF mathematical model is expressed by the surge, sway, heave, roll, pitch, and yaw motions for pure loss of stability in stern quartering waves in the reference (Lu et al., 2020). The surge, sway, yaw, and roll motions refer to the well-established models (Yasukawa & Yoshimura, 2015; Umeda et al., 2016) as shown in Eqs. (1)–(4), respectively. The heave and pitch motions are expressed in Eq. (5) and (6), respectively. The heave and pitch motions are calculated at each constant forward speed applied to an upright hull by a strip theory method using an enhanced integrating method of direct line integral to solve the velocity potential (Kashiwagi et al., 2010). The time-domain heave and pitch motions are calculated according to the relative position of the ship to waves as shown in Eqs. (7) and (8), respectively. The control equation for course-keeping by steering is added in the 6-DOF mathematical model as shown in Eq. (9).

$$(m + m_x)\dot{u} - (m + m_y)vr = X_H + X_R + X_P + X_W \quad (1)$$

$$(m + m_y)\dot{v} + (m + m_x)ur = Y_H + Y_R + Y_W \quad (2)$$

$$(I_{zz} + J_{zz})\dot{r} = N_H + N_R + N_W \quad (3)$$

$$\begin{aligned} (I_{xx} + J_{xx})\dot{p} - m_x z_H ur - m_y z_H \dot{v} \\ = K_H + K_R + K_W - D_{lf} \\ - D(\dot{\varphi}) - W \cdot GZ_{W_FK}(\xi_G/\lambda, \zeta_G(t), \theta(t), \chi, \varphi) \end{aligned} \quad (4)$$

$$\begin{aligned} (m + A_{33}(u))\ddot{\zeta} + B_{33}(u)\dot{\zeta} + C_{33}\dot{\zeta} + A_{35}(u)\ddot{\theta} \\ + B_{35}(u)\dot{\theta} + C_{35}\theta = F_3^{FK}(u) + F_3^{DF}(u) \end{aligned} \quad (5)$$

$$\begin{aligned} (I_{yy} + A_{55}(u))\ddot{\theta} + B_{55}(u)\dot{\theta} + C_{55}\theta + A_{53}(u)\ddot{\zeta} \\ + B_{53}(u)\dot{\zeta} + B_{53}\zeta = F_5^{FK}(u) + F_5^{DF}(u) \end{aligned} \quad (6)$$

$$\zeta_G(t) = \zeta_{Ga}(u) \cos [2\pi \cdot (\xi_G/\lambda) - \delta_H(u)] \quad (7)$$

$$\theta(t) = \theta_a(u) \cos [2\pi \cdot (\xi_G/\lambda) - \delta_\theta(u)] \quad (8)$$

$$\dot{\delta} = \{-\delta - K_P(\chi - \chi_C) - K_P T_{Dr}\}/T_E \quad (9)$$

The subscript H, R, P, and W refer to hull, rudder, propeller, and wave, respectively. Eqs. (7) and (8) are seakeeping mathematical models, and their symbols are listed with the traditional seakeeping method as follows.

$\zeta_G(t)$: heave displacement; $\theta(t)$: pitch angle; F_3^{FK} , F_3^{DF} : wave exciting force on heave direction including Froude-Krylov component and diffraction component; F_5^{FK} , F_5^{DF} : wave exciting moment on pitch direction including Froude-Krylov component and diffraction component; $\zeta_{Ga}(u)$, $\delta_H(u)$: amplitude and initial phase of heaving when the ship's forward speed is u ; and $\theta_a(u)$, $\delta_\theta(u)$: amplitude and initial phase of pitching when the ship's forward speed is u . The dot denotes the differentiation with time. A_{ij} , B_{ij} , and C_{ij} are coupling coefficients for added mass, damping, and restoring coefficients, respectively.

Subscripts 3 and 5 denote heave and pitch directions, respectively.

Experimental Method for Pure Loss of Stability

The ship model was driven by propellers in stern quartering seas in the free-running experiment. The roll, pitch, and yaw angles were measured by an optical fiber gyroscope placed on the ship model and the roll, pitch, yaw, and rudder angles and the propeller rotation speed was recorded by an onboard system which is connected with an onshore control computer wirelessly. The wave elevation was measured at the middle position of the basin by a servo-needle wave height sensor attached to a steel bridge which is 78 m in length and spans over the basin.

Free roll decay tests in calm water were conducted to obtain roll damping coefficients. The speed is a key factor for pure loss of stability. Here the nominal Froude number (Fn) is used for the experiment of pure loss of stability in stern quartering waves by using the same specified propeller rate as in calm water. The specified propeller rate corresponding to one nominal speed in calm water is determined by measuring the instantaneous position of the model ship with a total station system.

First, the model is kept near the wave maker manually by two workmen sitting on the carriage. The initial heading of the model is kept referring to the steel bridge which can rotate about its center, up to 45 degrees. Next, the wave-making system starts to generate waves. Then, the propeller revolutions increase up to the specified value according to the order received from the onshore control computer. When the wave train propagates far enough, the model is released free near one wave crest with its initial heading, and then the model automatically runs in stern quartering waves with its specified propeller rate and autopilot course by a course keeping system. The course keeping system includes the 6-DOF optical fiber gyroscope installed on the ship model and a PD control system is used for course keeping. The latter reacts according to the bias between the yaw angle from

wave direction measured by the gyroscope and the yaw angle of autopilot course and the yaw velocity measured by the gyroscope. When the ship model is free running in calm water, a disturbance of yaw angle is made, and then the rudder gain is set by the experience according to the reaction of course keeping in calm water.

The principal particulars and body plan of the ONR tumblehome are shown in Table 1 and Fig. 2, respectively. The ship model in the free running experiment is shown Fig. 3.

The Effect of Wave on Roll Restoring Variation

When the midship section is located on the crest in following seas, the metacentric height is reduced and may be even negative.

The righting arm in calm water GZ , the restoring variations in waves with the static balance method GZ_W -static and with the strip method at different constant forward speeds GZ_W (for $Fn = 0.0, 0.1$ and 0.3) are shown in Fig. 4. The stability loss at the wave crest is significant, and if the state of stability loss at the crest exists long enough, the ship may capsize.

Pure Loss of Stability,
Fig. 2 The ONR
tumblehome lines

Pure Loss of Stability, Fig. 3 The ship model in the free-running experiment

The Effect of Constant Speed on Pure Loss of Stability

The righting arm in calm water GZ and the restoring variations in waves GZ_w at different constant forward speeds are shown in Fig. 5. The encounter period becomes larger as the ship increases its forward speed, and the state of stability loss at the wave crest becomes larger.

The roll angle due to pure loss of stability at different constant forward speeds is shown in Fig. 6, and the roll angle becomes larger as the ship forward speed increases because the state of

stability loss at the crest becomes larger as shown in Fig. 5. But the state of stability loss at the crest is not long enough to result in capsizing.

The Effect of Surge Motion on Pure Loss of Stability

The nominal velocity of the ship at $F_n = 0.3$, the actual velocity of the ship and the wave velocity are shown in Fig. 7. The nominal velocity of the ship is much smaller than the wave velocity, and the maximum actual velocity of the ship is also smaller than the wave velocity. The forward speed is varied in a large range around the nominal speed of the ship due to the surge motion, and the state at the crest exists longer than that at the trough.

The righting arm in calm water GZ and the restoring variations in waves GZ_w with surge and without surge are shown in Fig. 8. The state of stability loss at the crest exists longer than that at the trough because the surge motion causes the state at the crest to exist longer than that at the trough as shown in Figs. 8 and 9.

As shown in Fig. 10, the mathematical model with 3-DOF of heave-roll-pitch coupled motions

Pure Loss of Stability,
Fig. 4 Restoring variation
in following seas with
 $\varphi = 10$ degrees, $\lambda/L_{pp} = 1.25$, $H/\lambda = 0.05$,
and $\chi = 0$ degree

Pure Loss of Stability,
Fig. 5 Time-domain
restoring variation in
following seas with
 $\varphi = 10$ degrees, $\lambda/L_{pp} = 1.25$, $H/\lambda = 0.05$,
and $\chi = 0$ degree

fails to predict capsizing because the state of stability loss at the crest is not long enough while that with 4-DOF of surge-heave-roll-pitch coupled motions could appropriately estimate the pure loss of stability in following seas. One key reason is that the state at the crest exists longer than that at the trough due to the surge motion and then the state of stability loss at the crest exists long enough. Therefore, the surge motion is important for predicting pure loss of stability in following seas.

The Effect of Initial Heel Angle on Pure Loss of Stability

Without an external heeling moment, once the wave crest passes the ship, the ship will finally return to the upright position with regained stability as shown in Fig. 10 with $\varphi = 0$ degree. The initial heeling angle is set as 8.6 degrees by cargo shift in the experiment and capsizing happens due to pure loss of stability as shown in Fig. 10. For investigating the effect of the initial heeling angle

Pure Loss of Stability,

Fig. 6 The effect of the constant speed on pure loss of stability with an initial heeling $\varphi = 8.6$ degrees, $\lambda/Lpp = 1.25$, $H/\lambda = 0.05$, and $\chi = 0$ degree

Pure Loss of Stability,

Fig. 7 Comparison between ship velocity and wave velocity with nominal $F_n = 0.3$, $\lambda/Lpp = 1.25$, $H/\lambda = 0.05$, and $\chi = 0$ degree

Pure Loss of Stability,

Fig. 8 The effect of surge motion on restoring variation with $\varphi = 10$ degree, $\lambda/Lpp = 1.25$, $H/\lambda = 0.05$, and $\chi = 0$ degree

Pure Loss of Stability,

Fig. 9 The effect of the sure motion on pure loss of stability with an initial heeling $\varphi = 8.6$ degrees, $\lambda/Lpp = 1.25$, $H/\lambda = 0.05$, and $\chi = 0$ degree

Pure Loss of Stability,

Fig. 10 The effect of initial heeling angles on pure loss of stability with $\lambda/Lpp = 1.25$, $H/\lambda = 0.05$, and $\chi = 0$ degree ($\varphi = 0, 2, 4, 6, 8$ degrees)

on pure loss of stability, simulations with different initial heeling angles are carried out as shown in Fig. 10. The roll angles become larger as the initial heeling angles increases, and capsizing happens at the critical speeds due to pure loss of stability. However, the ship could be captured by a wave crest when the ship has a very small initial heeling angle in following seas at a high speed. That is to say, the ship reaches the speed of the wave in this case.

manoeuvring force in the sway direction underestimates roll angles and fails to correctly predict capsizing range of critical ship speeds as shown in Fig. 11. This is due to its negative contributions to the roll moment as shown in Fig. 12. The calculated results with the coupling forces in the roll direction due to the manoeuvring force in the yaw direction are smaller than without it, as shown in Fig. 11. This is due to its positive contribution to the roll moment as shown in Fig. 13.

The Effect of the Coupling Forces from the Maneuvering Forces in the Sway and Yaw Directions in Stern Quartering Waves

The 6-DOF mathematical model without the coupling forces in the roll direction due to the

The Type of Roll Motions During Pure Loss of Stability

The experimental results of yaw, roll, pitch motions, and rudder angle in stern quartering waves are shown in Fig. 14.

Pure Loss of Stability,

Fig. 11 Comparison of maximum roll angle as a function of the F_n between the experimental results and calculated results with the 6 DOF with and without centrifugal force in roll direction due to the manoeuvring forces in the sway and yaw directions with $\lambda/L_{pp} = 1.25$, $H/\lambda = 0.05$, and $\chi = 30$ degrees

Pure Loss of Stability,

Fig. 12 The contribution to the rolling moments from the coupling force in the roll direction due to manoeuvring motions in the sway direction

Pure Loss of Stability,

Fig. 13 The contribution to the rolling moments from the coupling force in the roll direction due to manoeuvring motions in the yaw direction

Pure Loss of Stability,

Fig. 14 Yaw, roll, pitch motions, and rudder angle in the free-running experiment with $\lambda/Lpp = 1.25$, $H/\lambda = 0.05$, and $\chi = 30$ degrees. (a) Stable roll motion far from the critical speed of pure loss of stability. (b) Unstable roll motion near the critical speed of pure loss of stability. (c) Capsizing due to coupled pure loss of stability and broaching

A stable periodic roll motion can be found when the ship speed is far from the critical speed of pure loss of stability as shown in Fig. 14a, while an unstable roll motion can be found when the ship speed is close to the critical speed, as shown in Fig. 14b. The capsizing due to pure loss of stability is shown in Fig. 14c, and the yaw angle subtracting the heading angle reaches 20 degrees and the rudder angle reaches the maximum 35 degrees when the ship capsizes. The capsizing occurs due to pure loss of stability before developing the larger yaw angle, i.e., the maximum rudder angle cannot correct the course and obviously broaching stops due to the capsizing of the model. This could be a new phenomenon of capsizing due to coupled pure loss of stability and broaching.

As parametric roll, resonant roll, unstable roll motions, and capsizing due to coupled pure loss of stability and broaching could exist during pure loss of stability, further research should be conducted in the future to shed some light on this complex phenomenon.

Recycling Regulations

Wanhai Xu, Enhao Wang and Xifeng Gao
State Key Laboratory of Hydraulic Engineering
Simulation and Safety, Tianjin University,
Tianjin, China

Definition

Recycling regulations are the laws, rules, and conventions issued by authorities which are utilized to regulate ship recycling. They are introduced in the attempt to prevent, reduce, minimize, and, to the

extent practicable, eliminate accidents, injuries, and other adverse effects on human health and the environment caused by ship recycling.

Scientific Fundamentals

Introduction

According to the European Commission (EC), around 1000 large end-of-life ships all over the world are dismantled every year to recycle the steel and equipment. Most of this ship recycling takes place in South Asia, often on tidal beaches and under dangerous conditions which lead to health risks and extensive pollution of coastal areas. In fact, old ships contain many hazardous materials including asbestos, polychlorinated biphenyls (PCBs), tributyltin, and large quantities of oils and oil sludge. In order to reduce those negative effects of this industry, some laws, rules, and conventions have been made by national and international institutions. Nowadays, the most widely used and famous ones among them are the Basel convention, the Hong Kong Convention, and the EU Ship Recycling Regulation.

The Basel convention on the Control of Transboundary Movements of Hazardous Wastes and Their Disposal, usually known as the Basel Convention, was open for signature on 22 March 1989 and entered into force on 5 May 1992. It is an international treaty that was designed to reduce the movements of hazardous wastes between nations and specifically to prevent transfer of

hazardous wastes from developed to less developed countries (LDCs). It does not, however, address the movement of radioactive wastes. The Convention is also intended to minimize the amount and toxicity of wastes generated, to ensure their environmentally sound management as closely as possible to the source of generation, and to assist LDCs in environmentally sound management of the hazardous and other wastes they generate. As of February 2018, 185 states and the European Union (EU) are parties to the Convention. Among them, Haiti and the United States have signed the Convention but not ratified it.

The Hong Kong International Convention for the Safe and Environmentally Sound Recycling of Ships (or the Hong Kong Convention, for short) was adopted on 15 May 2009 by an IMO Diplomatic Conference of the International Maritime Organization (IMO) held in Hong Kong, China. This Convention covers the design, construction, operation, and preparation of ships so as to facilitate a sustainable ship recycling without compromising the safety and operational efficiency of ships. It also regulates the establishment of an appropriate enforcement mechanism for ship recycling, incorporating certification, and reporting requirements. From 2011, the IMO has developed several guidelines to assist the States Parties in the early implementation of the Convention's technical standards.

The EU Ship Recycling Regulation (1257/2013) entered into force on 30 December 2013 to reduce the negative impacts related to the recycling of EU-flagged ships, especially in South Asia. The Regulation is based on the Hong Kong Convention and aims to implement the Convention quickly, without waiting for its ratification and entry into force. To speed up the formal entry into force of the Hong Kong Convention, the Commission proposal for a Ship Recycling Regulation was accompanied by a draft decision requiring member states to ratify the Hong Kong Convention.

History

Pressure demanding a safer and a more environmentally friendly ship recycling industry has been building up over past decades and has found outlets among politicians and administrations, who

have looked for ways to regulate ship recycling with international common standards. The first attempt at addressing the problem was to try to implement "The Basel Convention on the Control of Transboundary Movements of Hazardous Wastes and their Disposal," which was adopted in 1989 and entered in force in 1992. The Basel Convention protects the human health and the environment against adverse effects that result from the generation and management of hazardous and other wastes. In particular, the Basel Convention focuses on regulating the transboundary movement of hazardous wastes in its effort to protect developing countries from importing hazardous wastes that they are unable to manage in an environmentally sound manner.

However, Basel does not establish a dedicated system for ships. Its provisions, and particularly its system of Prior Informed Consent designating a State of export, did not envisage ships. This has created difficulties in enforcing the Convention to end-of-life ships, especially in the European Union where the Basel Convention is implemented along with an amendment forbidding the export of hazardous wastes to non-OECD countries. Examples of cases where serious difficulties were experienced include the Otapan, the Sea Beirut, the Sandrien, the Margaret Hill, the Tor Anglia, the Onyx, and others. As early as October 2004, the seventh Conference of the Parties to the Basel Convention, in its decision VII/26, invited IMO to consider the establishment in its regulations of mandatory requirements that ensure an equivalent level of control as established under the Basel Convention and also ensure the environmentally sound management of ship dismantling, and "which might include pre-decontamination within its scope."

In 2003, the IMO adopted the IMO Guidelines on Ship Recycling (International Maritime Organisation 2003) and later in 2004 published for the Guidelines for the Development of the Ship Recycling Plan (International Maritime Organisation 2004). The International Labour Organization (ILO) published guidelines regarding safety and health issues in shipbreaking in 2004 which were subsequently translated into the local languages of major ship recycling countries (International Labour Organisation 2008).

Cooperation between IMO, ILO, and the Basel Convention Secretariat resulted in the establishment of a joint working group in 2005 in order to coordinate each party's activities and reduce regulatory overlaps (International Maritime Organisation 2005). A ship recycling conference organized by Lloyd's List in April 2005 discussed inter alia the necessity of a mandatory system.

The EU adopted its "Waste Shipment Regulation" (WSR) which was fully transposed and implemented from both the Basel Convention and the Basel Ban Amendment in 2006. In 2007, the EC published the "Green Paper on Better Ship Dismantling," which was further elaborated in the report "An Integrated Maritime Policy for the European Union" (European Commission 2007) and finalized in the document "An EU Strategy for Better Ship Dismantling" in late 2008 (European Commission 2008).

Prior to this, as early as January 2008, IMO published its "Draft Convention on Safe and Environmentally Sound Recycling of Ships." About the same time, the International Organization for Standardization (ISO) launched a new series of standards with regard to the recycling of ships (Engels 2013). It took just over 3 years since IMO agreed to develop a "new legally binding instrument on ship recycling" through an assembly resolution in December 2005 to develop the "Hong Kong International Convention for the Safe and Environmentally Sound Recycling of Ships," which is also known as the Hong Kong Convention (International Maritime Organisation 2009). And the Hong Kong Convention was finally adopted at a diplomatic conference held in Hong Kong in May 2009. On 30 December 2013, the EU Ship Recycling Regulation (1257/2013) (European Union 2013) which was based on the Hong Kong Convention entered into force.

Key Applications

Hong Kong Convention

Structure

As its core, the Hong Kong Convention contains 21 articles and an annex comprising of another 26 regulations stipulating general provisions as

well as specific requirements for ships, ship recycling facilities, and reports. This annex is followed by additional seven appendices containing a particular range of forms and checklists which are supposed to facilitate compliance with the provisions of the Hong Kong Convention. Furthermore, seven guidelines have been developed under the auspices of the IMO which relate to the implementation of a specific set of major obligations (Engels 2013). Figure 1 clearly depicts the basic structure of it.

Applicability

The Hong Kong Convention applies to "ship" and to "ship recycling facilities" of parties. Here, "ship" means a vessel of any type whatsoever operating or having operated in the marine environment and includes submersibles, floating craft, floating platforms, self-elevating platforms, floating storage units (FSUs), and floating production storage and offloading units (FPSOs), including a vessel stripped of equipment or being towed. And "ship recycling facilities" means a defined area that is a site, yard, or facility used for the recycling of ships. However, ships less than 500 GT, warships, naval auxiliaries, or other ships "owned or operated by a Party and used, for the time being, only on government non-commercial service" and ships that are "operating throughout their life only in waters subject to the sovereignty or jurisdiction of the State whose flag the ship is entitled to fly," if recycled in the same state where they have operated, are exempted from its terms. Even so, each Party shall adopt appropriate measures to ensure such ships act in a manner consistent with this Convention, so far as is reasonable and practicable. With respect to non-Parties ships, Parties shall apply the requirements of this Convention in a manner so as not to afford any favorable treatment (Engels 2013).

"Ship recycling" is defined by the Hong Kong Convention as "the activity of complete or partial dismantling of a ship at a Ship Recycling Facility in order to recover components and materials for reprocessing and re-use, whilst taking care of hazardous and other materials, and includes associated operations such as storage and treatment of components and materials on site, but not their further processing or disposal in separate facilities" (Puthucherril 2010). Therefore, the scope of

Recycling Regulations, Fig. 1 Structure of the Hong Kong convention

the convention is confined only to activities like scrapping and storage in the recycling yard and does not extend to the remaining steps in the recycling chain.

Key Objectives

The Hong Kong Convention is applied to prevent, reduce, minimize, and, to the extent practicable, eliminate accidents, injuries, and other adverse effects on human health and the environment caused by Ship Recycling and enhance ship safety, protection of human health and the environment throughout a ship's operating life.

Major Obligations

Major obligations of the Convention stipulate requirements for ships, requirements for ship recycling facilities, and reporting requirements. Requirements for ships may generally be divided into three parts:

- (1) Provisions addressing the problem of hazardous materials such as Regulation 4 and Regulation 5
- (2) Regulation 9 on the establishment of a ship recycling plan

- (3) The far-ranging Regulation 10 on the establishment of a number of different surveys

Requirements for Ship Recycling Facilities Regulations 15–23 affect ship-recycling facilities by stating certain standards which must be complied with Regulations 17 and 18 addressing the general requirements and the ship recycling facility plan are central to the regulating chapter on ship recycling facilities.

Regulations 24 and 25 contain notification and reporting requirements, thus comprising the final category of obligations. They primarily address the ship recycling facility but require a certain quality of cooperation by the ship owner. By regulating the whole ship recycling process from the intention of the ship owner to recycle a ship until the completion of the recycling procedure and by constantly involving official and private stakeholders, these regulations essentially cover also the recycling process from “cradle to grave.”

Entry into Force

This Convention shall enter into force 24 months after the date on which the following conditions are met (Mikelis 2010):

- (1) Not less than 15 States have either signed it without reservation as to ratification, acceptance or approval, or have deposited the requisite instrument of ratification, acceptance, approval or accession in accordance with Article 16;
- (2) The combined merchant fleets of the States mentioned in paragraph 1.1 constitute not less than 40% of the gross tonnage of the world's merchant shipping; and
- (3) The combined maximum annual ship recycling volume of the States mentioned in paragraph 1.1 during the preceding 10 years constitutes not less than 3% of the gross tonnage of the combined merchant shipping of the same States.

1989 Basel Convention

Basic Scheme

The Basel Convention applies to “transboundary movement” of “hazardous wastes.” The transport is considered “transboundary movement” when it involves any movement of hazardous wastes or other wastes, from one national jurisdiction of one state to or through the national jurisdiction of another state. The waste is “hazardous waste” as is listed in Annex I of the Basel Convention, unless they do not contain the characteristics listed in Annex III.

The Basel Convention has proved to be a basis for actions against substandard shipping in developing countries, which has in some cases forced an improvement in practices. However, the Basel Convention regime has been criticized throughout its operation for being ineffective in solving the problems related to ships (University of Southampton 2013).

Applicability

Whether ships sent and/or sold for recycling fall within the regulatory scope of the Basel Convention, is contingent upon three elements:

- (1) The ships have to be classified as waste.
- (2) The ships have to be subject to transboundary movement.
- (3) Both the State of Export and the State of Import have to be parties to the Basel Convention.

Generally, the Basel Convention is open and broad in its scope of application in order to encompass as many different kinds of wastes as theoretically and practically feasible.

Objectives

The primary objectives of the Basel Convention include minimizing the generation and transboundary movement of hazardous and other wastes and ensuring environmentally sound management of these wastes.

The Parties to the Basel Convention are obliged to minimize the generation of hazardous wastes and to promote adequate disposal within the state where such wastes are generated. The goal is to prevent dumping of toxic wastes onto developing countries. This goal is sought accomplished by reducing the generation of wastes and increase the capacity of the generating state to dispose of its own wastes (University of Southampton 2013).

Main Obligations

It is of note that the Convention places a general prohibition on the exportation or importation of wastes between Parties and non-Parties. The exception to this rule is where the waste is subject to another treaty that does not take away from the Basel Convention. According to the definition as provided by the Basel Convention, ships sent for recycling operations fall, in principle, within the scope of the Basel Convention.

If a State of Export has been established, then it will need to comply with Article 6 and its “prior informed consent” (PIC) regime.

Article 4 of the Basel Convention calls for an overall reduction of waste generation. By encouraging countries to keep wastes within their boundaries and as close as possible to its source of generation, the internal pressures should provide incentives for waste reduction and pollution prevention. Parties are generally prohibited from exporting covered wastes to, or import covered wastes from, non-parties to the convention.

According to Article 12, Parties are directed to adopt a protocol that establishes liability rules and procedures that are appropriate for damage that comes from the movement of hazardous wastes across borders.

Besides, there are some party obligations under the Basel Ban Amendment (Decision III/1). The Basel Ban obligation states that all Annex VII Parties have a special obligation to “prohibit all transboundary movements of hazardous wastes which are destined for operations according to Annex IV A to States not listed in Annex VII.”

Other Related Regulations

1982 UNCLOS

The 1982 United Nations Convention on the Law of the Sea (UNCLOS) establishes for its States Parties an overarching framework of rights and obligations relating to maritime affairs whose provisions on the protection of the marine environment (Part XII), according to many states, reflect rules of international customary law. The convention’s overall significance is explicitly recognized by the Hong Kong Convention. As stipulated by the preamble of UNCLOS, its objective is to establish a form of constitutional framework for the oceans focusing on the role of sovereign states within and toward the marine environment with the main objective of preserving sustainability. The fact that UNCLOS is a framework convention means that it has to be filled with substance by other instruments, both regionally and globally (Engels 2013).

1998 Rotterdam Convention

The Rotterdam Convention on the Prior Informed Consent Procedure for Certain Hazardous Chemicals and Pesticides in International Trade promotes a regulatory regime concerned with transboundary movements of particular hazardous chemicals.

This convention is of particular relevance in the ship recycling context as it serves as an example of a specific set of relevant principles and concepts, such as prior informed consent, which have been agreed upon at the international level regarding transboundary trade with certain chemicals and pesticides. Hence, these considerations might also be relevant with regard to ship recycling, especially if one considers the principal PIC procedure as a means of safeguarding states’ sovereignty.

1972/1996 London Convention

The London Convention on the Prevention of Marine Pollution by Dumping of Wastes and Other Matter, which is planned to be replaced by its Protocol after successful ratification, is an international instrument which aims at preventing “the pollution of the sea by the dumping of waste and other matter that is liable to create hazards to human health, to harm living resources and marine life, to damage amenities or to interfere with other legitimate uses of the sea.” The London Convention is not directly applicable to ship recycling. The convention and its protocol may rather be considered as a complement to ship recycling initiatives insofar as both abandoning ships and dumping them on the high sea still is considered by some actors as a mean of manage ships at the end of their final life cycle.

International Standards and Guidelines

A number of standardization organizations have been providing sets of relevant international and technical instruments, thus inter alia contributing to “harmonization of environmental standards, primarily by facilitating corporate behavior changes.” The most well-known standards are those developed and issued by the International Organization for Standardization (ISO). It uses a similar procedure to develop standards, guidelines, and related information as the OECD and may therefore also be labelled an instance of “network governance.” For ship recycling, the series of standards under ISO 9.000, ISO 14.000, and ISO 30.000 are of particular relevance.

European Initiatives in the Fields of Ship Recycling

Applicability

The territorial scope of the treaty defined in Articles 52 and 355 TFEU³⁴⁸ limits the scope of direct regulatory measures available to the EU in the field of ship recycling. However, the flag state jurisdiction provides just such an example of extraterritorial jurisdiction, which is one of the fundamental exemptions. Therefore, where these competencies have been conferred to the EU, the EU law would be applicable, regardless of

whether the ship is located within member states' waters. Additionally, via port state jurisdiction, the EU legislation could also be made applicable to all ships of foreign registries calling at ports of EU member states.

Objectives

The overall objective of European initiatives in the field of ship recycling is to "contribute to safer and more environmentally sound treatment of end-of-life ships worldwide." In the present situation, and with special consideration for the Hong Kong Convention, the EU measures may thus be based upon provisions for the protection of the environment, provisions aiming at improving the working environment, and provisions on the safety of transport at sea.

Fundamental Principles

According to Article 191.2 TFEU, environmental measures of the EU shall be based on inter alia, the Precautionary Principle and the Polluter Pays Principle.

Potentially hazardous materials shall be identified ex ante as "potential sources of concern," they shall be listed in inventories which shall accompany each ship in a "properly maintained and updated" fashion throughout its operating life in order to facilitate later recycling operations and minimize related risks to the environment and/or human health, and, with regard to supplementary data regarding hazardous materials, upon request an evaluation shall be conducted "of the association between the Hazardous Material in question and the likelihood that it will lead to significant adverse effects on human health or the environment." All these aspects can only be fully understood in the context of the Precautionary Principle, as various legal obligations are established requiring action at a point of time when there is no imminent environmental threat. In addition, capacity building via transfer of knowledge might also "raise the standards of protection and precaution in the countries concerned." As a matter of course, the EU will take these considerations into account when enacting related legislation.

The principle of "Polluter Pays," namely, the 1992 Rio Declaration, Principle 16 states: National

authorities should endeavor to promote the internalization of environmental costs and the use of economic instruments, taking into account the approach that the polluter should, in principle, bear the cost of pollution, with due regard to the public interest and without distorting international trade and investment. Of far greater importance in practice, at least from a European point of view, the principle of "Polluter Pays" has found its way into numerous judgments of the European Court of Justice in recent years. Additionally, the European Commission explicitly is of the opinion that environmentally sound ship recycling is first and foremost the producer's responsibility and should therefore follow the Polluter Pays Principle.

Waste Shipment Regulation (No 1013/2006)

The EU fully transposed and implemented both the Basel Convention and the Basel Ban Amendment by adopting its "Waste Shipment Regulation" (WSR). According to this regulation, ship recycling capacity currently available to ships flying the flags of the EU member states is considerably restricted, effectively to the existing Turkish and British ship recycling facilities. Therefore, the practice is that most of European ship owners obviously make use of loopholes and prefer to contract with substandard Asian ship recycling facilities in order not to face the costs and/or administrative burdens resulting from the application of the WSR.

The EU Ship Recycling Regulation (No 1257/2013)

Structure

The EU Ship Recycling Regulation mainly contains 32 articles, comprising of 6 titles and 2 annexes which give the list of hazardous material and their control measures. Figure 2 demonstrates the basic structure of the EU Ship Recycling Regulation.

Applicability

The Ship Recycling Regulation applies to large commercial seagoing vessels flying the flag of an EU member state and to ships flying the flag of a third country calling at the EU ports or

Recycling Regulations,

Fig. 2 Structure of the EU ship recycling regulation

anchorages. In order to ensure legal clarity and avoid administrative burdens, ships flying the flag of a member state covered by the new legislation would be excluded from the scope of the Waste Shipment Regulation (EC 1013/2006).

According to the new rules, the installation or use of certain hazardous materials on ships, such as asbestos, ozone-depleting substances, PCBs, PFOS, and anti-fouling compounds, will be prohibited or restricted. Each new ship flying the flag of an EU member state (or a ship flying a flag of the third country calling at the EU ports or anchorages) will be required to have on board an inventory of hazardous materials.

Objectives

As is shown in Article 1, the main purpose of this Regulation is to prevent, reduce, minimize, and, to the extent practicable, eliminate accidents, injuries, and other adverse effects on human health and the environment caused by ship recycling. The purpose of this Regulation is to enhance safety and the protection of human health and of the Union marine environment throughout a

ship's life cycle, in particular to ensure that hazardous wastes from such ship recycling is subject to environmentally sound management.

Specially, the Regulation aims to reduce significantly the negative impacts related to the recycling of the EU-flagged ships, especially in South Asia without creating unnecessary economic burdens (Explanatory note 1.2).

Major Obligations

Obligations of Owners of "the EU flagged ships" with respect to:

- (1) Recycling only at a ship recycling facility on the "European List" (which shall be initially published not later than 31 December 2016): see Articles 6 and 16.
- (2) Preparation of a ship for recycling: see Article 6.
- (3) Ship recycling plan: see Article 7.
- (4) Surveys and certificates: see Articles 8, 9, and 10.

For requirements for Ship Recycling Facilities to be included in the "European List," see Articles 13–16 of the Regulation.

Recycling Regulations, Fig. 3 Relationships between typical regulations

Entry into Force and Date of Application

Unlike the Hong Kong Convention, the EU Ship Recycling Regulation makes a distinction between the date of its entry into force and the date of application.

The regulation has entered into force on 30 December, 2013, 2 days after its publication in the Office Journal of the EU (Mikelis 2013).

The date of application is the date after which ships under the scope of the EU Ship Recycling Regulation will start having to have an Inventory of Hazardous Materials (IHM), to be surveyed, certificated, and recycled in line with the requirements of the EU. The EU Ship Recycling Regulation shall apply from the earlier of the following two dates, but not earlier than 31 December 2015 shall apply:

- (1) 6 months after the date that the combined maximum annual ship recycling output of the ship recycling facilities included in the European List constitutes not less than 2.5 million light displacement tones (LDT).
- (2) On 31 December 2018.

There are also some provisions of the European Regulations shall apply from different dates which are explained in Article 32(2–4). Please refer to the original text for more information.

Relationships Between Typical Regulations

Regulations are not independent of each other. Transposition from one regulation or its key mechanisms to binding obligations of another one is common in the process of developing better recycling regulations. Existed conventions and guidelines can be serviced as the basis to the new regulations by giving some pertinent

definitions and basic principles. For example, IMO's guidelines and the Basel Convention provide guidance to the Hong Kong Convention, facilitating both its understanding and implementation. The Basel Convention published the “Technical Guidelines for the Environmentally Sound Management of the Full and Partial Dismantling of Ships” in 2003 which is a predecessor to the Convention (de Larrucea and Mihailovici 2011). Similarly, parts of the EU legislation of recycling are transposed from the Hong Kong Convention and the Basel Convention as shown in Fig. 3.

As for the current existed and used regulations, coordination have been made between their conflicts by adding conflict clauses and other pertinent provisions. Besides, amendments or even some new guidelines and regulations are born from the conflicts and unreasonable places in original regulations.

In short, the make and amendment of one regulation are related to others which have similar scopes and conflicts to it.

Reefing

Haiming Zhu and Zunfeng Du

Department of Naval Architecture and Ocean Engineering, School of Civil Engineering, Tianjin University, Tianjin, China

Definition

Reefing refers to a process of building artificial reefs. An artificial reef is a man-made underwater structure, typically built to promote marine life in areas with a generally featureless bottom, to control erosion, block ship passage, or improve surfing. The typical methods are sinking oil rigs (through the Rigs-to-Reefs program); scuttling ships, rocks, wood, metal; or deploying rubble or construction debris. Other artificial reefs are purposely built (e.g., the reef balls) from PVC or concrete. Shipwrecks may become artificial reefs when preserved on the sea floor. Regardless of construction method, artificial reefs generally provide hard surfaces where algae and invertebrates such as barnacles, corals, and oysters attach; the accumulation of attached marine life in turn provides intricate structure and food for assemblages of fish (Wikipedia 2019).

Scientific Fundamentals

History

The construction of artificial reefs can be traced to ancient times. Persians built artificial reefs for blocking the mouth of the Tigris River to thwart Indian pirates (Williams 2006), and Romans built reefs across the mouth of the Carthaginian harbor in Sicily to trap enemy ships (Hess et al. 2001). Artificial reefs to increase fish yields or for algaculture began no later than the seventeenth

century in Japan, where rubble and rocks were used to grow kelp. The earliest recorded artificial reef in the USA is from the 1830s, when fishermen used interlaced logs to build artificial reefs (Williams 2006). The interest in establishing coastal artificial reefs increased rapidly in the USA during the twentieth century due to the subsequent increase in recreational and commercial fishing and its expenditures (Bull and Love 2019). It was estimated that about 90% of the intentionally deployed wrecks to serve as artificial reefs correspond to the US locations (Ilieva et al. 2019).

The Colonization of Reefing

The colonization of artificial reefs is done progressively. In the beginning, devoid of any form of life, they are rapidly colonized by weed and animal classes like sponges, hydroids, bryozoans, bivalve shells, barnacles, acids, anemones, halcyons, and gorgons and finally, after a few years, by corals with calcareous skeletons like *Acropora*, *Montipora*, *Pocillopora*, and *Pavonia*. This encrusting fauna and flora provide food for sedentary and mobile animals like sea cucumbers, starfishes, sea urchins, crabs, and squids as well as small fishes like snappers, butterflyfish, *Priacanthus*, triggerfish, demoiselle, sergeant major, etc. In turn, these small fish attract pelagic and predator species such as hinds, morays, kingfishes, mackerels, barracudas, etc. Finally, it formed a marine biological system.

Rigs-to-Reefs

Common practice for platform removal uses explosives or mechanical techniques below the seafloor to sever the jacket so that it can be pulled out of water and taken to shore for recycling and/or a landfill (Bull and Love 2019). There are other options that entail reefing the submerged sections of the platform structure (BSEE 2017). Rigs-to-Reefs (RTR) is the process of converting end-of-life oil and gas platforms into artificial reefs. Such reefs have been created from oil rigs in the USA, Brunei, and Malaysia. Offshore oil and gas platforms first began functioning as artificial reefs in 1947 when Kerr-McGee, an American energy company, completed the world's first

commercially successful oil well 11 miles off Louisiana's shore. In the USA, where the practice started and is most common, Rigs-to-Reefs is a nationwide program developed by the former Minerals Management Service (MMS), now Bureau of Safety and Environmental Enforcement (BSEE), of the US Department of the Interior. And the vast networks of energy platforms in the Gulf of Mexico form what is widely regarded as the largest man-made reef in the world, so the Rigs-to-Reefs initiative first began in the Gulf of Mexico as a way to preserve the habitats that form on the rigs' steel scaffolding.

There are three methods of platform removal and reefing to have been used in the RTR process: (a) tow-and-place platform, (b) partial removal in place platform, and (c) topple-in-place platform.

The first and most common removal method, in deepwater applications, involves the use of explosives inside the jacket legs, 15 ft below the mudline. Once the jacket legs are severed by the explosives, the structure is toppled over in a horizontal position on the bottom. This method offers the donor lower costs and time savings. The disadvantage to the use of explosives is the potential mortality of sea turtles, marine mammals, and fish that might be associated with structures, though large numbers of fish are killed, the overall impact to the population was relatively small.

The second removal option involves the partial removal of the upper portion of the jacket and placing it on the seafloor next to the standing bottom portion of the jacket. This method is particularly beneficial with deepwater structures that are converted into reefs. The standing vertical portion of the structure, which must provide at least 85 ft of navigable clearance, remains in place and continues to provide beneficial habitat for a large number of pelagic and other reef fish originally associated with the platform. Also, the upper portion that is removed provides an equal or slightly lower profile to compliment the standing section and increases the overall surface area of the structure for habitat enhancement. This type of removal requires a waiver from the Minerals Management Service. The waivers are required, since existing regulations require severing of the 55-jacket legs 15 ft below the mudline. For

deepwater operations, this method significantly reduces the removal costs and risks for divers.

The third removal option involves divers cutting the jacket legs below the mudline using explosives. Once the legs are severed, the entire structure can be lifted from the sea floor using a derrick barge, towed to a new permitted location, and placed on the bottom in a horizontal or vertical position. Mechanical or abrasive cutters can also be used to cut the legs. This method is typically only used in water depths less than 100 ft. Water depths in excess of 100 ft would significantly increase the risks to divers. There, however, would be no adverse impacts to associated living marine resources. This method is also expensive, labor-intensive, and time-consuming. Although there was no monetary savings using this method, instead of using explosives, the turtles, fish, and encrusting organisms were transported along with the structures to the new reef site.

Benefits

First, oil and gas platforms have proven to be excellent artificial reef material. The National Plan cites five major characteristics or standards for artificial reef materials. These standards, together with siting and management, generally determine the success or failure of an artificial reef project. These include function, compatibility, durability, stability, and availability, and oil and gas platforms appear to possess all these characteristics.

Second, it is well documented that oil and gas platforms function well as artificial reefs by providing habitat for a variety of species, since many of these species are habitat limited. And the steel members of the platform provide the necessary hard bottom substrate for many of the encrusting organisms critically important in developing reef habitat.

Third, oil and gas platforms have proven to be compatible with the marine environment, since generally only the submerged jacket of the structure or that portion of the platform that has never come in contact with hydrocarbons is used.

Forth, oil and gas platforms are also very durable and stable, rarely if ever moving from where

they were placed. And these platforms also appear to be relatively durable and have a life span of 300 years.

Last, during the reefing, partial mechanical removal methods using divers or abrasive cutting tools have provided a method for transferring platforms into reefs with the highest profile in the water column with the least impact on the natural resource and decrease the dangers to sea turtles and marine mammals.

Drawbacks

There are several disadvantages to using oil and gas platforms as artificial reefs. One of the disadvantages is the expense in removing these structures. Derrick barge rates currently run between \$50 thousand to \$100 thousand a day depending on the lifting capabilities of the barge. The size of the structure to be removed determines the size of barge required. This, however, may be turned into a benefit if the savings realized, by not having to take it to shore, can be shared with the entity accepting the ultimate responsibility for the structure. To date, however, the oil and gas industry has dealt only with established state-recognized reef programs. In some areas permitting and meeting state law requirements and the ability to satisfy liability requirements have prevented fishing clubs and private individuals from acquiring platforms as reefs.

Another disadvantage is the method of removal. Currently, state-of-the-art techniques required to sever these structures from the seafloor involve the use of explosives. The concern over the use of explosives stems from their potential impact on endangered sea turtles and marine mammals.

Scuttling Ships

Reefing by scuttling ships is the deliberate sinking of a ship by allowing water to flow into the hull, which can provide an artificial reef for divers and marine life. This can be achieved in several ways – seacocks or hatches can be opened to the sea, or holes may be ripped into the hull with brute force or with explosives.

In the USA, scrap materials of opportunity, deployed without assembly or much modification,

still account for a large portion of reef construction materials. Vessels have served as components of most state artificial reef programs. Where available, and where depth conditions allow for deployment, vessels remain an important reef material to many reef managers, particularly on the Atlantic coast. The earliest record of intentionally sinking vessels for artificial reef fishing is 1935 when four vessels were sunk by the Cape May Wildwood Party Boat Association. Dozens of steel-hulled ships sunk in coastal continental shelf waters along the Atlantic and Gulf Coasts during World War II still provide commercial and recreational fishing opportunities and diving enjoyment more than 60 years later.

To prepare a hulk for sinking as an artificial reef, several things must be done to make it safe for the marine environment and divers. To protect the environment, the ship is purged of all oils, hydraulic fluids, and dangerous chemicals such as PCBs. Much of the superstructure is removed to prevent the hazard of it eventually caving in from corrosion. Similarly, the interior of the ship is gutted of all structures that corrode quickly and would be dangerous to divers if they came loose. The ship is thoroughly cleaned, often with the help of volunteers interested in diving. A significant part of the cost of preparing and sinking the ship comes from scrapping the contents of the ship, including valuable materials such as copper wiring. The hulk's suitability as a diving site is enhanced by cutting openings in its hull and interior bulkheads to allow divers access. The preparation phase removes a significant amount of weight, so the ship sits higher in the water than normal. The ship must be carefully weighed down by filling some sections with water as makeshift ballast tanks to prevent excessive rolling in port or during towing. The ship is towed to the sinking location, usually in shallow waters.

Benefit

First, vessels make interesting diving locations for both recreational divers and technical deep-diving mixed-gas users. Vessels are also regularly utilized as angling sites by recreational fishermen and the charter fishing industry.

Second, vessels used as artificial reefs can, alone or in conjunction with other types of artificial reefs, generate reef-related economic contributions to coastal counties. Especially steel-hulled vessels, when selected for sound hull integrity, are considered durable artificial reef material when placed at depths and orientations that insure stability in major storm events.

Third, due to high vertical profile, the artificial reefs built by vessels attract both pelagic and demersal fishes. Vertical surfaces produce upwelling conditions, current shadows, and other current speed and direction alterations that are attractive to schooling forage fishes, which in turn attract species of commercial and recreational importance, resulting in increased catch rates for fishermen.

Forth, like other artificial reef material, it can augment benthic structure which locally increases shelter opportunities and reef fish carrying capacity in locations where natural structure is sparse or create structure which is more preferable or attractive to certain fish species than locally less complex hard bottom.

Drawback

First, vessels were originally designed and utilized for purposes other than artificial reef construction. They can be contaminated with pollutants, including PCBs, radioactive control dials, petroleum products, lead, mercury, zinc, and asbestos. Hazardous wastes and other pollutants are difficult and expensive to remove from ships.

Besides, vessels typically provide proportionately less shelter for demersal fishes and invertebrates than other materials of comparable total volume. This is because the large hull and deck surfaces provide few, if any, holes and crevices. This lack of shelter from predation greatly reduces the usefulness of a ship as nursery for the production of fishes and invertebrates. Also, while a high vertical profile can be attractive to pelagic fish species, unless a vessel hull is extensively modified to allow for access, water circulation, and light penetration, most of the interior of the vessel is not utilized by marine fishes and macroinvertebrates.

Last, high vertical profile may render some vessels more prone to movement and/or structural damage due to ocean current and wave surge generated by severe storm conditions. And its durability may be compromised by salvage operations during the cleaning process or by the explosives sometimes used to sink these vessels.

Although there are some drawbacks in the reefing by them, they are the most common method of building artificial reefs, compared to its advantages.

Definition

Reliability refers to the ability of the product to complete the specified function under the specified conditions and within the specified time. *Safety* refers to the ability of structure to bear various possible actions under normal construction and normal use conditions and to maintain the necessary overall stability when and after accidental events.

Introduction

Offshore engineering is a field of engineering that principally deals with the methods for recovering hydrocarbon resources from deep beneath the seabed, from the installation stage and operation of fixed platform structures as well as floating platforms, their operation, and the laying of pipelines and supplementary oil/gas transport systems.

Recently, phenomenal advancement in science and engineering has been witnessed as a result of rapid growth of the offshore field, particularly in the exploration and development of offshore oil and gas fields in deep waters of the oceans.

A competition increase in the areas of development and installation of innovative offshore

structures, systems, and facilities has led to the question of reliability to be a matter of great interest. In addition during designing, installation and operation of offshore structures technical problems arise which relates to safety and environmental issues. However, offshore structures must be designed, built, installed, and operated with an aim that they work reliably, safely, and efficiently for designed periods of time without maintenance and with limited supervision.

Generally, reliability is taken to mean operation without failure. When an offshore system as a whole does not do what it was designed for, even though none of its components fails, but then it is still charged against the system reliability. A good example of reliability would be an offshore structure that can continue to operate safely when a system or component fails. It is good to know that a good engineering always involves a balance between safety and reliability.

A commonly used definition for a safety of an offshore structure is that it is a state of an offshore structure being safe from undergoing or causing hurt, injury, or loss. Safety is attained by using reliable structures, components, systems, and procedures. The comparative definitions can be summarized by defining reliability as a measure of confidence that the system produces accurate and consistent results, contrary to safety which can be defined as a measure of confidence that the system will not cause accidents.

Reliability as a Probability

De Carlo (2013) gives the definition of reliability as the probability that a component (or an entire system) will perform its function for a specified period of time, when operating in its design environment. Thus he gives his arguments that the elements necessary for the definition of reliability are an unambiguous criterion for judging whether something is working or not and the exact definition of environmental conditions and usage.

Parnami et al. (2012) also defines reliability as the probability that a component, device, system, or process will perform its intended function without failure for a given time when operated correctly in a specified environment. He also adds

that reliability deals with decreasing the frequency of failures over a time interval and is a measure of the probability for failure-free operation during a given interval.

From definition reliability can be mathematically expressed as

$$R(T) = \Pr\{T > t\} = \int_t^{\infty} f(x)dx$$

where $f(x)$ is the failure probability density function and (t) is the length of the period of time (which is assumed to start from time zero).

It is easy to represent “probability of failure” as a symbol or value in an equation, but it is almost impossible to predict its true magnitude in practice, which is massively multivariate. Therefore, having the equation for reliability does not begin to equal having an accurate predictive measurement of reliability.

Key Concepts of Reliability

In order to start a discussion on basics of reliability, coverage of the key concepts of probability becomes crucial. Three important independent concepts can be derived as follows from the definition:

1. Time duration
2. Environmental conditions of use that cause a failure or a fault
3. Functioning parameter value or range that consist the error concept

Fjeld (1978) elaborates that probabilistic reliability is the only meaningful concept which can be used to obtain a logical and objective distribution of risks and safety requirements in the offshore industry. He gives a clear description that probabilistic reliability is a tool for specifying criteria for how safe offshore engineering works should be and for evaluating design and operational requirements from probabilistic criteria for the installation as a whole.

Reliability is restricted to operation under stated conditions. This constraint is necessary

since it is impossible to design a system for unlimited conditions. For example, the deep-sea petroleum Gulf of Mexico oil spill, largest marine oil spill in history, caused by an explosion on the Deepwater Horizon oil rig as a result of failure of subsea blowout preventer stack. Thus, there are extremely strict requirements for safety and reliability in offshore and marine engineering.

Objectives of Reliability in Engineering

Simiu and Smith (1984) state that the objective of structural reliability is to develop design criteria and verification procedures aimed at ensuring that structures built according to specifications will perform acceptably from a safety and serviceability viewpoint.

Structural reliability is also applied to individual components, which are potentially applicable to offshore engineering problems. These include the estimation of failure probabilities, safety indices, and safety (or load and resistance) factors. It is also an essential tool in the risk analysis of the total installation of a structure.

However, it has been stated in Ersdal and Lengen (2002) that the most obvious choice for establishing quantitative probabilities of failure is to use a structural reliability analysis, taking into account the variability of the nature, uncertainties in load, uncertainties in capacities, and often inspections, maintenance, reserve strength, and air gap.

Applying the highlights of decreasing order of priority of the objectives of reliability in engineering from (O'Connor and Kleyner 2012), we can apply the objectives as follows:

1. To prevent or to reduce the likelihood or frequency of failures by applying engineering knowledge and specialist techniques
2. To identify and correct the roots of failures that occurs regardless of the efforts to prevent them
3. To determine ways of coping with failures that occurs, if their causes have not been corrected
4. To apply methods for estimating the likely reliability of new designs, and for analyzing reliability data

From their work more clarification is given on the need to emphasis on order of priority as the most effective way of working, in terms of minimizing costs and generating reliable offshore structures. The ability to understand and anticipate the possible causes of failures forms the primary skill and knowledge of how to prevent them. Having the knowledge of the methods that can be used for analyzing designs and data is of much importance.

Reliability Theory and Models

Gertsbakh (2000) states that an important step in the formal development of the reliability theory is introducing the notion of lifetime. It is defined as the time elapsed since the “birth” of the system till the appearance of certain event which we call “failure.”

Fjeld (1978) modern probabilistic reliability theory seems to be the logical tool to obtain an objective distribution of risks. Failure sources which cannot be considered random and therefore cannot be treated by reliability theory/must be eliminated by control and inspection. Random errors cannot be eliminated by inspection and must be covered by safety factors.

From the review of many researches, it is clear that for better understanding of reliability, we need to develop models that show the relation between various components of a system. This aids in tracing the cause of failure or faults of a given component in an event of a system becoming unreliable.

Parnami et al. (2012) emphasizes that in system reliability analysis, it is important to model the relationship between various items as well as the reliability of the individual items in order to determine the reliability of the system as a whole.

Barlow (2003) highlights that in order to study reliability, you need to transform reality into a model, which allows the analysis by applying laws and analyzing its behavior.

Reliability models are broadly classified into two:

1. Static models
2. Dynamic models

Static models assume that a failure does not result in the occurrence of other faults, whereas dynamic models assume that some failures, so-called primary failures, promote the emergence of secondary and tertiary faults, with a cascading effect.

A diagram-based model for reliability analysis gives a visual representation of the system's components thus giving a good understanding of the system.

Figure 1 below shows diagram-based models frequently used in reliability analysis. Consisting of the following:

1. Reliability block diagrams (RBDs)
2. Failure modes and effects analysis (FMEA)
3. Fault tree analysis (FTA)
4. Event tree analysis (ETA)
5. Decision tree approach (DTA)
6. Root cause analysis (RCA)

Design for Reliability

Design for reliability (DfR) is a process that incorporates tools and procedures to ensure that a system attain its reliability requirements, under its use environment, for the duration of its lifetime. DfR is mostly used as part of an overall design for excellence (DfX) strategy. DfR is implemented in the design stage of a structure to proactively improve the reliability of a given system.

There are mainly two approaches that can be used in the design for reliability. These are:

1. Statistics-based approach (i.e., MTBF)
2. Physics of failure-based approach

Statistics-Based Approach (i.e., MTBF)

In this approach reliability design begins with the development of a (structure) model; it uses block diagrams and fault tree analysis models to provide a graphical means of evaluating the relationships between various parts of the system. These models use predictions based on failure rates taken from historical data.

Physics of Failure-Based Approach

Physics of failure is the method that depends on understanding the physical static and dynamic failure mechanisms. It accounts for variation in load, strength, and stress that lead to failure with a high level of detail, made possible with the use of modern finite element method (FEM) software programs that can handle complex geometries and mechanisms such as creep, stress relaxation, fatigue, and probabilistic design.

Reliability Testing

“Failure” definition is key aspect of reliability testing. There are many situations where it is not

Reliability and Safety in Offshore Engineering, Fig. 1 Reliability block diagrams

clear whether a failure is really the fault of an offshore structure. Probability estimation can be done from previous data sets or through reliability testing. The sole purpose of reliability testing is to discover potential hitches with the design as early as possible and, ultimately, provide confidence that the system attain its reliability requirements.

Reliability plays a key role in the evaluation of cost-effectiveness of offshore structure systems. Reliability is measured against the standard of requirements of a given offshore structure system's specification. Thus, the methodology used to calculate one offshore structure system's reliability depends on its configuration.

Reliability is not only achieved by mathematics and statistics. Reliability can be attained through process and reliability testing. Reliability testing involves exercising an application so that failures are detected and eliminated before an offshore structure is stationed. MTBF (mean time between failures) for repairable components of an offshore structure system and MTTF (mean time to failure) for non-repairable components can be used to calculate reliability.

Reliability tests can be done on the offshore structure system for the most likely situations under conditions of normal usage and validate that the expected service can be provided by a given offshore structure. As time progresses, more complicated tests can be applied to reveal subtler defects.

Benefits of Reliability in Offshore Engineering

Some of the benefits of reliability are listed as follows:

Safety: Some offshore structures fail due to unintended or unsafe conditions leading to injury or loss of life. Reliability engineering tools assist in identifying and minimizing safety risks before their occurrence.

Time: Failures which are not planned for cost time to resolve. Using reliability concepts we can reduce failures and loss of time.

Design: Enhancing the design team's reliability engineering capabilities through training and working closely with reliability professionals to make decisions having fully considered the impact on reliability of the offshore structures. This reduces the need for expensive redesign or rework costs to address reliability related design errors at a later stage.

Expectation: Offshore structures work under environmental and use conditions. Creating an offshore structure that matches the expectations imposed by the operators of the structures permits the structure to work as expected. Getting to know the conditions well allows the design to be met without over designing thus optimizing the structure cost and operator's satisfaction.

Distribution: With fewer failures and optimized maintenance work of offshore structure results in fewer spare parts in the overall logistics system. This minimizes the costs for logistics, transportation, and storage for spare parts and eventually service labor costs are minimized.

Liability: Offshore structure can cause the loss of property. Failure minimization and damage mitigation caused by any failure reduces the exposure to liability for the property loss.

Conclusion

Reliability in offshore engineering is a broad topic to be covered since the offshore structures are complex in nature. A lot of areas which need further research work by the researchers in the area of reliability of these offshore structures, more so in uncertainty quantification, failure analysis of complex systems and life testing of offshore structure and equipment.

Definition

In the development of a product, it is important to ensure its reliability in the design stage, which enables the concept of reliability throughout the full life cycle of product design, operation, maintenance, and decommission. Such a design method is called reliability-based design (RBD). RBD methods take safety factors into consideration to account for uncertainties, so that established target reliability levels for products can be achieved. The main research contents of RBD include uncertainty theory, reliability analysis, and reliability-based design optimization (RBDO).

Scientific Fundamentals

Uncertainty Theory

At present, uncertainty is mainly divided into two categories, including aleatory uncertainty and epistemic uncertainty (Oberkampff et al. 2004). Aleatory uncertainty describes the nature of random variations inherent in physical systems or environments, and epistemic uncertainty is originated from the lack of knowledge or information. The relationship between mastery degree on knowledge and uncertainty is shown in Fig. 1.

With the development of science and technology, the understanding of a certain natural phenomenon becomes more and more profound, so the epistemic uncertainty will gradually decrease with the increase of knowledge. However, many natural phenomena have inherent contingency, and sometimes the phenomena are contrary to the conclusions obtained through the existing scientific observation, which reflects the inherent uncertainty of natural phenomena (i.e., aleatory uncertainty). The mathematical theory used to describe uncertainty is the basis for dealing with uncertainty in practical problems.

The most popular method of describing aleatory uncertainty is probability theory. The founder of classical probability theory (CPT) was the Swiss mathematician Bernoulli, who established the first limit theorem named Bernoulli law of large number in probability theory. In 1933,

Reliability-Based Design (RBD), Fig. 1 The relationship between cognition and uncertainty

A.N. Kolmogorov summarized the basic properties and relations of events and their probabilities with the ideas of set theory and measure theory, established the axiomatic system of probability, and laid the theoretical foundation of probability theory (Durrett 2019). For epistemic uncertainty, the widely used description methods are interval theory (Moore 1966), evidence theory (Shafer 1976) and possibility theory (Zadeh 1978), generalized information theory (Klir and Wierman 2013), etc. With the development of uncertainty theory, many scientists are working on a unified uncertainty theory that can be used to describe both aleatory and epistemic uncertainties. Cui and Blockley (1990) combined probability theory and interval theory to obtain interval probability theory (IPT) and employed it as a method to measure the credibility of evidence in knowledge system. Based on quantum decision theory (QDT), Papageorgiou and Kamperi (2017) proposed a quantum-based decision-making model which can be employed in engineering design; this model can also capture the complexity of human decision making under uncertainty. The proposed model is able to describe not just the aleatory uncertainty but also the subconscious intuitive feelings and cognitions of the decision makers (i.e., epistemic uncertainty).

Reliability Analysis

The ability of an engineering system or product to accomplish a specified task under certain conditions and specific time is referred to as reliability. In the design stage, the specified function of an engineering system can be expressed as a function of the input variable $X = (x_1, x_2, \dots, x_n)$, which is usually called the state function $g(X)$. The value of state function $g(X)$ can be used to judge whether

the function of engineering system can meet the design requirements. The most commonly used judgment logic is two-valued logic: when the state function exceeds a certain state, the engineering system cannot meet the requirements of a certain function stipulated in the design. This particular state is called the limit state of the function. If the engineering system can meet the functional requirements specified in the design, the system is reliable, otherwise, the system is unreliable. The reliability of the engineering system is usually divided according to the zero point of the state function:

$$\begin{cases} \text{reliable} & g(X) < 0 \\ \text{unreliable} & g(X) \geq 0 \end{cases} \quad (1)$$

Then the judgment function of two-valued logic can be expressed as:

$$I(g(X)) = \begin{cases} 1 & g(X) < 0 \\ 0 & g(X) \geq 0 \end{cases} \quad (2)$$

Reliability analysis is closely related to the uncertainty theory used to describe the uncertain variables. When the uncertain variable X is described by different uncertainty theories, the reliability analysis method of system state function $g(X)$ is also different. When uncertain variables are described as random numbers by classical probability theory, reliability analysis is called probabilistic reliability analysis. When uncertain variables are described as fuzzy numbers by fuzzy set theory, reliability analysis is named fuzzy reliability analysis.

There are two main reliability analysis methods, including probabilistic reliability analysis method and fuzzy reliability analysis method.

Probabilistic Reliability Analysis Method

In probability theory, the uncertain variable $X = (x_1, x_2, \dots, x_n)$ is considered as a random variable obeying a certain probability density distribution, and the value of state function $g(X)$ of the system is also a random variable. In this case, the failure probability P_f of the system can be expressed as:

$$P_f = \int \dots \int I(g(X)) f_X(x) dx_1 \dots dx_n \quad (3)$$

where $f_X(x)$ represents the joint probability density function of the random variable X .

It can be observed from eq. (1) that the calculation of failure probability is a multidimensional integration process, and it is very difficult to calculate this integral in practical problems with high dimension. Therefore, various approximate methods for reliability estimation have been established; these approaches are called reliability assessment methods (Moffitt 2010). At present, reliability assessment methods can be divided into four main categories:

- (1) Reliability Index Approach (RIA): First Order Reliability Method (FORM), Second Order Reliability Method (SORM), etc.
- (2) Monte Carlo method: Crude Monte Carlo (CMC), Improved Monte Carlo method (IMC), etc.
- (3) Performance Measure Approach (PMA): Mean Value (MV), Advanced Mean Value (AMV), Hybrid Mean Value (HMV), etc.
- (4) Approximation model method: Response Surface Method (RSM), Neural network (NN), etc.

Fuzzy Reliability Analysis Method

When the judgment logic function is fuzzy membership function or the uncertainty variable is described by fuzzy theory, the reliability analysis is called fuzzy reliability analysis. Fuzzy reliability analysis methods can be divided into two types:

- (1) Reliability analysis based on fuzzy logic
- (2) Reliability analysis based on fuzzy variables

Because the development of fuzzy theory is not mature and the calculation amount of the fuzzy theory is far beyond the acceptable range, the fuzzy reliability analysis method has not reached the level of practical engineering applications.

Reliability Based Design Optimization (RBDO)

The reliability of engineering products is closely related to the design, manufacture, assembly, and management in the process of product development, among which design plays a decisive role in the reliability of engineering products. RBDO adopts the uncertainty theory based on probability theory, and the research focus of RBDO is the influence of uncertain factors on the constraint function of the engineering product design optimization model. In the objective function, value of the uncertain variable is replaced by its mean value. In general, the optimal design points of engineering problems are located on the boundary of feasible region, and the uncertainty change of design parameters or design variables is likely to make the optimal design points fall out of feasible region due to the disturbance. As mentioned above, since most of the constraints that work are important mandatory index requirements such as safety, this means that there is a great possibility that the optimization design point cannot meet the mandatory index requirements of the actual engineering system, that is, the reliability of the optimization design is not up to standard, so it is important to research the reliability-based design optimization methods (Pan and Cui 2020). In RBDO, the optimization model can be formulated as:

$$\begin{aligned} & \min f(d, u_X) \\ & s.t. \quad P(g_u(d, X) < 0) < P_f^t \\ & \quad g_d(d) \leq 0 \\ & \quad d^l \leq d \leq d^u \\ & \quad u^l \leq u_X \leq u^u \\ & \quad \sigma \text{ or cov is known} \end{aligned} \quad (4)$$

where d is called design variables, X refers to the random variable and u_X refers to the mean value of X , g_u and g_d represent the uncertain constraint function and the deterministic constraint function,

respectively. $P(g_u(d, X) < 0) < P'_f$ is called probabilistic constraints. Probabilistic constraints are the biggest difference between RBDO optimization model and deterministic optimization model. There are three common RBDO algorithms to solve RBDO problems, including double loop reliability-based design optimization (DLRBDO), sequential optimization and reliability assessment (SORA), and safety factor based sequential optimization and reliability assessment (SFSORA).

DLRBDO

As shown in Fig. 2, DLRBDO algorithm (Allen and Maute 2004) includes the process of reliability analysis, so the algorithm includes two nested iterative processes. The external iteration is the optimization algorithm and the internal iteration is reliability analysis. Since DLRBDO algorithm will lead to a sharp increase in computation, the approximate model can be used to replace the original high-precision state function. DLRBDO algorithm based on approximate model has been widely used in engineering field (Gayton et al. 2003).

SORA

SORA algorithm was first proposed by Du and Chen (2002). In SORA algorithm, the relationship

between optimization and reliability analysis is no longer nested, but sequential. Reliability analysis is executed after the finish of optimization process, which can greatly reduce the calculation amount.

SFSORA

In engineering design, the most common method to ensure reliability is the safety factor method. Pan and Cui (2020) combined SORA algorithm with the safety factor method and put forward a new SORA algorithm based on safety factor, which is called SFSORA.

Key Applications

With the development of uncertainty theories and reliability analysis methods, reliability-based design methods have been widely applied to various fields. Based on probability theory, Ronold and Larsen (2000) presented a reliability-based design method and applied it to analyze the safety of a wind-turbine rotor blade against failure in ultimate loading. By using perturbation method, second moment method, and reliability-based design method, Zhang and Liu (2002) put forward a practical and effective method for the reliability-based design of automobile components. Zhang

Reliability-Based Design (RBD), Fig. 2 Illustration of double loop reliability-based design optimization

et al. (2003) presented a new reliability-based design methodology by combining the perturbation method and reliability-based design theory, and the proposed methodology was applied to the reliability-based design of gear pairs, and the theoretical formulae of reliability-based design of gear pairs were obtained. Phoon et al. (2003) developed a reliability-based design framework for transmission line structure foundations, and the role of the proposed RBD method is presented within the context of geotechnical limit state design. A design methodology that combines reliability-based design optimization and high-fidelity aeroelastic simulations for the analysis and design of aeroelastic structures is proposed by Allen and Maute (2004). In this work, to account for uncertainties in design and operating conditions, a first-order reliability method (FORM) is used to approximate the system reliability. To develop a strategy for solving reliability-based design optimization (RBDO) problems that remains applicable when the performance models are expensive to evaluate, Dubourg et al. (2011) proposed a surrogate model based RBDO method by using the kriging model, and the effective of the strategy is validated by comparing with other approaches available in the literature on three academic examples in the field of structural mechanics. A methodology for reliability-based design and assessment of an ageing fixed steel offshore structure was established by Mat Soom et al. (2016) to support detailed re-assessment applied to the management of the structure's safety, integrity analysis, and reliability by evaluating the loading acting on the structure. By integrating the coupled corrosion fatigue model into the reliability-based design optimization, Saad et al. (2016) applied the proposed RBDO method to the life cycle cost of the structure subject to deterioration processes of fatigue and corrosion. To maximize the characteristics of tailor rolled blank (TRB) structures, a multiobjective and multicase reliability-based design optimization (MOMCRBDO) was developed by Sun et al. (2017) to optimize the TRB hat-shaped structure, and the radial basis function (RBF) metamodel was adopted to approximate the responses of objectives and

constraints, the nondominated sorting genetic algorithm II (NSGA-II), coupled with Monte Carlo Simulation (MCS), was employed to seek optimal reliability solutions. Luo and Hu (2018) presented an efficient reliability-based design tool for stone-filled crib seawalls, in this work, the first-order reliability method is integrated into spreadsheet to facilitate the reliability analysis for practical application. Homaei and Najafzadeh (2020) proposed a reliability-based probabilistic evaluation framework to assess the effect of various parameters on the reliability for the scour depth to be less than a specific value.

Definition

The **Remotely Operated Vehicle (ROV)** is a kind of submersible, remotely operated by a crew aboard a supporting vessel, floating platform, or on land. Generally, ROV works on the principle of teleoperation where slave system, in this case it is the ROV body, interacts with hazardous extreme environment and a master system, in this case human operator, is placed at safe and comfortable location (Agba [1995](#); Costa et al. [2012](#)). Therefore, the ROV can be remotely controlled to perform the underwater activities with the manipulators and other tooling capabilities. The umbilical cable can supply electrical power to the ROV body; meanwhile, the ROV body can also return the video or other data information to the supporting vessel through the umbilical cable.

Scientific Fundamentals

ROVs have the largest number in the world, which is the most widely used, most complex, and most powerful submersible as compared to other kinds. In addition, ROVs have the characteristics of strong work applicability, function flexibly extended, no constraint on the work endurance, no risk of the crews, etc. With the umbilical cable, ROVs can perform the

complicated tasks with higher strength and longer duration on a fixed point under the very severe deep sea circumstance (Tao and Chen 2016).

System Composition

The system composition of an ROV is closely related to its use and working depth. Generally, the ROV system includes eight subsystems, which are ROV body, tether management system (TMS), tether/umbilical cable, launch & recovery system, deck operation & control system, power supply system, manipulator & tooling package. Among all these subsystems, the ROV body, umbilical cable, deck or aboard operation & control system, and power supply system are compulsory (Lian et al. 2015). In addition, other configurations can be added depending on the system size and work demands, for instance, the drilling machine and sampler.

The whole ROV system can also be divided into the underwater and above-water parts. The above-water part consists of launch & recovery system, the deck operation & control system, umbilical winch and power supply system; the underwater part consists of the ROV body, tether management system (TMS), manipulator & tooling package (Lian et al. 2015). Undoubtedly, the two parts are connected by the umbilical cable, which can transmit the control signal and power from the supporting vessel to the ROV body. Meanwhile, the ROV body can also return the captured video and other information to the supporting vessel. In the comprehensive consideration of the water depth and work demanding, the ROV body can

be launched and recovered through either the single umbilical cable or the TMS. Diagram of the system composition for the ROV is shown in Fig. 1, and system configuration for the ROV body is shown in Fig. 2 (Lian et al. 2015).

ROV Types

As for ROV types, there are many different classifications. Depending on size and weight, ROVs can be classified into micro-sized ROV, small-sized ROV, medium-sized ROV, large-sized ROV, and super-sized ROV. According to uses, ROVs can be divided into observation-class ROV and work-class ROV. They can also be divided into work-class ROV and heavy duty work-class ROV depending on their work abilities and divided into free-swimming ROV and bottom-crawling ROV according to the motion mode; furthermore, they can also be divided into electric ROV and hydraulic ROV depending on the driving mode (Chen et al. 2018).

Small-sized ROVs are relatively simple to control and they are mainly used for underwater observation; therefore, they are observation-class ROV. Medium-sized ROVs commonly have the weight around hundreds of kilograms. Besides the observation function, they are also equipped with manipulators and sonar system; thus, they can dosimple works and are ability to fix their position. Large-sized ROVs always have the weight of several tons. They have very powerful propulsion system, and are equipped with a lot of devices, such as underwater TV, sonar, tooling package, multifunctional manipulators, etc. Super-sized ROVs have the weight of up

Remotely Operated Vehicle (ROV), Fig. 1 Typical system composition of ROVs

Remotely Operated Vehicle (ROV), Fig. 2 System composition of the ROV body (Lian et al. 2015)

to dozens of tons, which are typically used for special underwater works, for instance, the pipeline burial. It needs to be mentioned that large-sized ROVs are capable of performing very complex heavy duty underwater works; therefore, they are currently the most widely used kind of ROVs on the exploitation of the offshore oil & gas field. Figure 3 shows the images of the ROVs with different size.

Historical Development

ROVs are the earliest developed and most widely applied submersible among all kinds of submersible. The earliest ROV was designed in 1953 by Dimitri Rebikoff and named as “POODLE,” which was mainly used in the study of archaeology. It had little impact on the ROV development, but it was the origin. Due to limitation of technologies in the early day, the ROVs had a lot of problems, such as leakage, noise, unstable performance, frequent maintenance, hydraulic system being prone to closing down, and so on (Christ 2013).

In 1961, the USA army developed a flexibly operated underwater video system “XN-3,” which finally evolved into the cable-controlled underwater research vehicle (CURV). Later, the army improved CURV, which also made a lot of great events. For instance, the CURV II salvaged a

nuclear bomb at the water depth of 869 m offshore the Spanish sea (Fig. 4a). In 1973, the CURV III was emergently sent from San Diego, USA, to Ireland and performed the deepest underwater rescue in history when it rescued two men trapped at depths of 480 m in the sea for 76 h. After that, the US Army also developed a lot of more complex tethered vehicles, including the first small-sized portable observation-class ROV “SNOOPY” (Fig. 4b), and subsequently a fully electric ROV “Electric SNOOPY” equipped with sonar and other sensors. Subsequently, the US Army has input a huge of money into the Hydro Products in San Diego, USA, which promoted the ROV industry to grow in leaps and bounds. At this time, one of the famous ROV is the “TORTUGA.”

In the whole year of 1974, only 20 ROVs were produced in the world, including the Fenland “PHOCAS,” Norway “SNURRE,” UK “CONSUB 01,” as well as the Soviet Union “CRAB-400” and “MANTA.” The ROV industry was still insufficient to pry the market occupied by the HOVs (human occupied vehicles) and divers. However, the great change came in the period till to the end of 1982; there were about 500 ROVs all over the world. There was also a great change on the funding source to produce these ROVs. From 1953 to 1974, 85% of the

Remotely Operated Vehicle (ROV), Fig. 3 ROVs with difference size: (a) small-sized ROVs, (b) China “HAIMA”-4500 ROV (Lian et al. 2015), and (c) the world’s biggest subsea robot SMD ultra trencher 1 (Machin 2011)

fund was provided by the government, whereas 96% of this fund for about 350 ROVs was provided by the private companies from 1974 to 1982.

At this time, the technology of ROV became matured and stable. The most important thing was that the ROV was accepted by a lot of marine companies. In 1983, there was even an international conference of ROV’83 with the theme of “A Technology Whose Time Has Come!” More advanced countries, such as USA, Canada, France, Italy, Netherland, Norway, Sweden, Germany, UK, and Japan, entered the ROV industry and produced more kinds of ROVs, including the micro-sized observation-class ROV. Some of these ROVs were also

possessed by the society association or academic and research organization.

Till the 1990s in the twentieth century, the technology of ROV had become quite matured, and the ROVs acted positively in most of the oceans and performed many kinds of complex works. The US Army’s CURV III could reach the 6128 m water depth, and their advanced tethered vehicle (ATV) even reached 7012 m below the sea surface. The ROV “KAIKO 11000” designed and manufactured by the Japan Agency for Marine-Earth Science and Technology (JAMSTEC) even reached the deepest area of the seabed in 1994 (Barry and Hashimoto 2009), the Mariana Trench of the Pacific Ocean. However, in 2003, it was lost in an ocean

Remotely Operated Vehicle (ROV), Fig. 4 (a) US Navy's CURV II vehicle, (b) US Navy's hydraulic SNOOPY, and (c) Schilling Robotics UHD

investigation due to the break of the neutral-buoyance umbilical cable. The booming offshore oil industry increased the demanding for the advanced submersibles, especially when the works, such as ocean floor drilling and exploitation, could not be finished by the divers due to the high water pressure in deep sea region, which forced the ocean oil industry and ROV developer to cooperate together. For instance, Schilling Robotics UHD ROV could perform a lot of very complex works, such as underwater stalling, operation, and maintenance (Fig. 4c).

In the twenty-first century, many ROV manufacturers started to develop the observation-class ROV and medium-sized ROV. As for the ROV education, the European and North American countries have held some training plans to fulfill the demand of ROV operation with the booming ROV industry. Marine Advanced Technology Education (MATE) center aims to encourage the high school and college-aged young engineers into the field of subsea robotics. Today,

the center has already sponsored several international competitions.

Key Technologies in Developing the Deep Sea ROV

Typically, the ROV is an interdisciplinary system. As for the ROV design, the engineer needs to consider the launch and recovery system, layout configuration of ROV body, propulsion system, maneuverability, as well as the work tools. Among all these design procedures, some of them are called as key technologies and will be introduced as follows:

1. Navigation and position technology

With the development of the modern satellites, to lock on a target on land or on the sea surface is relatively easier, while it is quite difficult to get the position of an object underwater. Therefore, the navigation and position is the first problem that should be solved when operating the ROV for sea bottom works.

The operator needs to know the current position of the ROV in the deep sea and the position the ROV is going to. Then the operator can lead the ROV to the next position.

2. Comprehensive control technology

The comprehensive control technology is mainly used to distribute the power for the whole system, to control and monitor devices, direction, video surveillance, lights, pan/tilt system, leakage of electricity, leakage of hydraulic oil, and so on. The comprehensive control system is designed with high technology and complex configuration. It is also the head of the ROV system and the key selling point in the ROV industry. The specific key technologies include system control, real-time data inspection, warning, emergency isolation, multidata merging, real-time attitude inspection, touch control, data record and analysis, auto-heading, auto-depth and auto-altitude navigation, etc.

3. Umbilical cable

As the important part connecting the ROV body to the sea surface support vessel, the umbilical cable functions as power transmission, communication, control command transmission, data transmission, launch, and recovery. Generally, the umbilical cable consists of optical fiber, electric cable, mechanical part, filler, Kevlar, and other materials, which are integrated through the way of helical winding. Therefore, the umbilical cable is on a high comprehensive level, has large mechanical strength, has good corrosion resistance, and can be repeatedly released and recovered. In addition, the umbilical cable can be designed/chosen according to the working depths. Generally, there are two kinds of umbilical cables, armored cable and neutral buoyancy cable. As the armored cable is so heavy that the length limitation is generally no longer than 6000 m. Undoubtedly, the umbilical cable is one of the key technologies which restricts the development of the 11,000 m ROV system. Thus, to develop the light, high strength, and abrasion-resistant umbilical cable, which can be repeatedly released and recovered, is the hot spot and trend in the future.

Key Applications

The ROV has a wide range of applications; some of the specific areas include survey and inspection, deep sea oil & gas production, deep sea mining, military, educational outreach, underwater photography, fisheries and aquaculture, civil construction, and public safety (Tao and Chen 2016; Chen et al. 2014).

Survey and Inspection

ROVs used for the survey and inspection are clearly observation-class ROVs or observation-class ROVs with payload option. ROVs are our eyes and hands in the deep sea. They can be used for many science and geological surveys, for instance, capturing the images of marine lives and sea floor, sediment sampling, marine life collection, geological drilling and sampling, water sampling, gauging the health index of marine lives and environment, estimating pollution level, searching for new living species and minerals, and so on. Figure 5 shows the images of marine lives observed by the ROVs.

Observation-class ROVs can also be used to locate and position the beacon markers, lay the seabed observation network and underwater structures, inspect pipeline, jacket and even the marine hull of vessels. These ROVs usually have the ability to hold their position in strong currents, and are equipped with manipulators, lighting lamp, camera, sonar, and strobe flasher.

Deep Sea Oil & Gas Field

Mission of ROVs in the deep sea oil & gas field is a traditional and important application (Shukla and Karki 2016). With steep depletion of major onshore and shallow-water-offshore oil fields, new search of fossil fuel is moving toward deep-water and ultra-deep water offshore fields. Previously, companies can employ the divers to do some inspection and installing work in the shallow-water-offshore oil & gas fields, while it is impossible in the deep water. In addition, replacement of divers with robotic devices to accomplish complex tasks is an unavoidable trend with automatization of the overall offshore oil & gas industry. ROVs are used for many

different purposes and the important tasks are listed as follows:

- **Site survey**
Observation-class ROVs are used to map the seabed before carrying out the activities of installation and drilling.
- **Drilling assistance**
Once oil & gas reserves are discovered, mobile drilling platforms such as drill-ship, jackup rig and submersible drilling rig are used to drill the exploratory well at reserve sites. Work-class ROVs are used to assist the drilling; the activities may include collecting fluid samples from seabed for analysis, retrieving a drilling riser connected to a blowout-preventer located on a sea bed, and real time drilling data interpretation for multiple holes in a single dive.
- **Inspection, maintenance, and repair**
Metallic offshore structures are naturally facing difficult environmental conditions (i.e., salty water and strong sea tides), inspection work of flaws, corrosion and related cleaning, grinding, installing, trenching, lifting, pulling, bolt handing, and equipment transport can be performed by work-class ROVs (Baker and Descamps 1999).
- **Mobile inspection**
Apart from submerged structures, the equipment on the sea surface (i.e., mobile floating platforms, permanent platforms, and ships) also need routine inspection by the observation-class ROVs to improve safety and efficiency of overall production facility. The specific works include inspecting the gauge reading, leakage and surface condition, etc.
- **Oil spill situations**
Oil spill can occur at any stage of petroleum industry (i.e., exploration, drilling, production, transportation, refining, and finally distribution) (Fingas 2012), which is one of the major crises for the oil & gas industry. It not only results in huge revenues losses but also severely damages ecological system of marine life. During these accidents, the ROVs with remote sensing, laser fluorosensors, microwave sensors, and other techniques can be

used for many activities such as regular surveillance, detection of spill, and helping in cleaning up operations after spill.

Deep Sea Mining

The deep sea mining has attracted more and more interests in the past decade, as the seabed is known to contain huge quantities of minerals. Recent discoveries have well illustrated that the rare earth deposits lied in the Pacific Ocean are estimated to be 80–100 billion metric tons. Take American Neptune Minerals for example, the company was established in 2011, which seeks to explore and mine the seafloor massive supplied deposit around volcanic arcs (Bogue 2015). It is known that exhaled supplied-rich mineralized fluids from the hydrothermal vents are often rich in gold, silver, copper, zinc, and lead around the volcano arc. Three unique seafloor production tools of an auxiliary cutter, a bulk cutter, and a collecting machine will be used to mine these massive deposits up to 1000 m. The auxiliary cutter and bulk cutter are used to flatten the rugged terrain close to the volcanic chimneys. Then the collecting machine sucks in the cut material, with the mine deposit harvested and pumped to a ship on the sea surface. A deep sea mining system schematic is shown in Fig. 6. The key components are the bulk cutter, a massive, tracked robotic device (Fig. 7) equipped with 4-m-wide cutting blades and driven remotely by two pilots in a control room on a surface vessel. Undoubtedly, they are also special kinds of ROVs.

Military

ROVs have been deployed by the navy more than half century, and a famous example as mentioned above was that the USA Navy's CURV II salvaged a nuclear bomb at the water depth of 869 m offshore the Spanish sea (Christ 2013). ROVs can help the navy to hunt and break the mines. Small-sized ROVs can also be used by the navy for coast guards and port authorities, and have been widely deployed for a variety of underwater inspection tasks, such as explosive ordnance disposal, meteorology, port security, mine countermeasures, maritime intelligence, surveillance, and reconnaissance.

Remotely Operated Vehicle (ROV), Fig. 6 Deep sea mining system (Bogue 2015)

Underwater Broadcast and Photography

Note that the time-duration for ROVs working in the dangerous and complex sea circumstances is unlimited. If evolved with HD cameras, the

observation-class ROVs can help the filmmakers to capture the footage (The Dark Secrets of the Lusitania 2016). A famous example for using ROVs to film the documentaries is the BBC

Remotely Operated Vehicle (ROV), Fig. 7 Robotic bulk cutter (Bogue 2015)

Wildlife Special Spy in the Huddle. In addition, the scientist or tourists can also use the small-sized and medium-sized ROVs to take photos of marine lives, coral or plants.

Fisheries and Aquaculture

Small-sized and medium-sized ROVs can be used in the fisheries and aquaculture. One of the typical services provided by the ROVs is to inspect the fish cages, the specific works include checking nets for holes, assuring the integrity of moorings for farms, and retrieving dead fish from the cage for health purposes (Christ 2013). In the shallow-water-offshore region, like the Shandong province of China, farmers keep a lot of sea cucumbers. The current is very strong and the water is turbid due to the mixture of sand from the rivers in this region, but this region is quite suitable for the sea cucumbers. There is a limit for divers to collect the sea cucumbers in a day due to the visibility, physical fitness, as well as the safety consideration. Another reason is that it is also very expensive to employ the divers. If evolved with sonars and suction manipulators, the ROV can collect the sea cucumber more efficiently than the divers. If countering the overall cost, the ROV will be cheaper than the divers.

Civil Construction

ROVs used for subsea civil construction are typically higher powered and specification work-class ROV; they are equipped with high pressure 7-function manipulators and tooling package. The specific tasks performed by the ROVs may include moving heavy pieces, guiding large construction pieces into place, laying and burying cables and pipelines, setting and pulling rigging, and setting mattresses, etc. (Christ 2013).

Public Safety

Public safety is clearly the realm of observation-class ROVs equipped with cameras, sonars, and other tooling capabilities. This mission typically involved periodic inspection and sweep of pier recreational water, first responder to perform search and rescue the public need, such as recreational boater drown, drown person in the recreational water, river or sea.

Definition

ROV is a kind of underwater robot used for underwater observation, inspection, and construction.

As the land resources are gradually exhausted, the ocean, which could provide the rich resources for human’s sustainable development, has been paid increasingly attention. The twenty-first century is recognized as the ocean century by the world. With the advantages of safety, economy, and high efficiency, underwater vehicles can replace human beings to complete high-intensity and heavy-duty underwater operations in a deep and high-risk environment. Hence, an underwater vehicle has become an indispensable equipment for understanding, developing, and utilizing the ocean. This paper mainly focuses on the classification, application, design, and development technologies of underwater vehicles.

Concept and Classification

Underwater vehicle is a mechanical and electrical device that can freely move in the water, equipped with a vision and perception system. Through the remote control or autonomous operation,

underwater vehicle utilizes manipulator or other tools to replace or assist human beings to complete underwater tasks (Christ and Wernli 2014).

Classification of Underwater Vehicles

Underwater vehicle can be classified into different types as follows:

- *Classified by functions:* According to different purposes, underwater vehicles can be divided into three categories, operation, observation, and measurement. Among them, the operation underwater vehicles with working manipulators are used for underwater operations such as rescue, salvage, cable laying, operation, and maintenance of offshore oil platform and other production systems. The observation underwater vehicles are nearly as same as the operation one, but they are mainly used to measure the parameters of the objects to be investigated. The measurement underwater vehicle uses cameras, video cameras, and sonar to observe the topography of sea floor or to search for underwater objects.
- *Classified by modes of motion:* According to different motion modes, underwater vehicles can be divided into three categories, floating, crawler, and walking. Most of the floating underwater vehicles are designed with zero buoyancy (or a little positive buoyancy), and the three-dimensional space motion underwater is relied on thrusters. Crawler underwater vehicles, which are driven by crawlers, are mostly used in seabed construction. The walking underwater vehicles use the walking mechanism to walk on the sea floor. At present, the walking underwater vehicle is still in the research and development stage, and few application cases are reported.
- *Classified by control mode:* Underwater vehicles fall into two basic categories: remotely operated vehicle (ROV) and autonomous underwater vehicle (AUV). The difference between ROV and AUV reflects in whether the underwater vehicle is tethered or not. ROV connects the mother ship of submersible by an umbilical cable, which not only transmits power downward but also controls signals

(from the mother ship to ROV) and data/images (from ROV to the mother ship) in real-time bidirectional transmission. However, there is no physical connection (no tether) between the AUV and the mother ship. The AUV relies on its own power, navigation and positioning sensing system, and intelligent control decision-making system to achieve autonomous navigation. Compared with ROV, AUV has many advantages, such as wide range of activities, deep diving, little risk of umbilical entanglement, ability of performing tasks in complex structures, no large deck support system required, and low operation and maintenance costs.

Design and Features of AUV and ROV

AUV: AUV is designed to withstand extreme pressure and maintain neutral buoyancy in the deep sea under extreme harsh conditions to reduce the required propulsion energy and improve the efficiency of the vehicle. Therefore, the overall structure of AUV is generally optimized to ensure streamlined shape design of AUV body and to find a balance point between limited volume and system power consumption and battery power consumption, carry sensors according to the design purpose, and maintain the longest endurance capability. In addition, AUV uses modular and standardized design to accomplish many different tasks. Since all mechanical and electronic interfaces inside the body are standard, the selected sensors can be quickly integrated into the load module, and the functions of the new sensors can be integrated into the software of the main system through a software toolkit to synchronize the data flow with the navigation status. As a result, the AUV has stronger endurance and load-carrying capabilities, more automated and safe release, and recovery systems.

AUV has strong endurance and load-carrying capacity, more automatic and safe release, and recovery system. The general basic components of AUV include (1) battery, (2) onboard detection equipment, (3) navigation and positioning system, (4) propulsion system, (5) communication system, (6) safety and security system, (7) release recovery system, and (8) deck workstation.

ROV: ROV system is mainly composed of support mother ship, deck console, deck power supply unit, ROV lifting system, umbilical cord cable, ROV body, robot, and working tools. It is powered and communicated by a surface mother ship through the umbilical cord cable connecting the ROV body; observed and operated by the mother ship staff through underwater video, sonar, and other special equipment; and can also operate underwater by a manipulator. Since it does not endanger personal safety and power is primarily provided by the mother ship, working underwater can theoretically be if possible. The ROV has hydraulic power system, propulsion system, cloud platform system, video and lighting system, navigation and positioning system, power supply and distribution system, and monitoring system. The underwater stability of ROV can be well maintained by hydrodynamic analysis, reasonable arrangement of installation position of each equipment, and adjustment of center of gravity by ballast block (Dan et al. 2010).

At present, the propulsion devices of underwater vehicles mainly include propeller thruster, hydraulic thruster, pump-jet thruster, magnetic fluid thruster, bionic thruster, track thruster, and so on. Propeller is generally used as the propulsion system of underwater vehicles. However, in some special environments, other types of propulsion systems are used, such as mining robots working under the sea, mostly crawler thrusters.

The characteristics of the two underwater vehicles are comprehensively compared as shown in Table 1.

Figure 1 shows two observable ROVs developed by author’s team. Figure 2 shows two AUVs developed by author’s team.

Application Fields of Underwater Vehicles

With the rapid ocean development, there are increasing number of underwater construction

Remotely Operated Vehicle (ROV) in Subsea Engineering, Table 1 The characteristics of AUV and ROV

and building projects. Underwater vehicles can perform observation, camera shooting, measurement, salvaging, and construction operations underwater, and hence they are widely used in ocean development. At present, underwater vehicles are widely applied in many engineering fields, such as underwater engineering, marine scientific investigation, salvaging, marine military, and fishery production.

Applications in Underwater Engineering

- *Underwater structure inspection:* Physical location detection and quality measurement of underwater structures, verification and inspection of laying conditions, damage and corrosion, inspection of drilling platforms, wellheads, dams, cracks, and safety conditions of pollution barriers and gates.
- *Underwater surveillance:* Monitor the operation and construction guidance of grouting, piling, trenching, felling, bulldozing, and other aspects of underwater civil engineering.
- *Submarine topography survey:* Map natural or man-made underwater objectives, seabed topography, and seabed profile.
- *Underwater facility cleaning:* Clean and repaint the surface of underwater facilities, clean oil rigs, remove rust, and paint hulls, pipelines, and underwater components.
- *Underwater target search and recognition:* Search and salvage specified objects underwater, sunken ships, abandoned equipment, equipment, etc.
- *Installation and maintenance of underwater facilities:* Install and maintain underwater pipeline cables, open valve, weld, cut and detonate, replace the sacrificial anode, etc.
- *Assist diver operation:* Assist diver operations, ensure the safety of divers, and transfer construction equipment to divers.

Applications in Marine Scientific Expeditions

- *Marine geological survey:* Record the microtopography of the ocean floor, draw a map of the sea floor, and collect sea floor patterns and rock samples. A 3500-meter ROV independently developed by China has observed a rare huge black chimney in the seamount region of the Eastern Pacific Ocean. During operation, a hydrothermal black chimney sample was obtained by a manipulator of ROV, which provides valuable information for ocean research.
- *Marine life expedition:* Measure the biological form on the seabed and collect biological samples.
- *Marine physics expedition:* Observe seawater aquifers, circulating water velocity, salinity, temperature, depth distribution, seawater specific gravity, etc.
- *Geophysical expedition:* Measure the earth magnetic field and investigate oil and gas deposits.
- *Marine acoustic survey:* Observe underwater acoustic characteristics, underwater reverberation, and acoustic models.

- *Geochemical expedition*: Observe the water temperature of the sea floor, the soil temperature of the sediment layer, and the pH value of the sediment.
- *Marine optics expedition*: Observe water transparency, natural light field distribution, light absorption intensity, etc.

Marine Military Applications

Military underwater vehicles may play a significant role in the naval battle, which may induce a new prospect in the future. Military underwater vehicles can perform a variety of tasks in maritime military confrontations, such as coastal reconnaissance, demining, anti-submarine, communications, and navigation. They make a possibility to quickly seize a military victory with minimal human casualties in naval battles. The functions of military underwater vehicles are listed as follows.

- *Underwater demining*: Underwater vehicle is an optimal equipment to perform anti-deminig operations. Compared with other anti-deminig devices, underwater vehicle has the advantages of low cost and good concealment.
- *Anti-submarine warfare*: Underwater vehicle can search and track submarines in coastal waters, narrow waterways, and straits. It has a better ability to search for submarines than surface ships and submarines. Underwater vehicles are also utilized to set traps for enemy ships in anti-submarine warfare (sonar confrontation, misleading direction).

ROV System Design

ROV System

ROV, a kind of unmanned underwater vehicle with cable remote control, generally consists of a deck unit (i.e., a control system), a winch retractable system, and a body. Its work flow is as follows: the operator sends orders through the control system, and the commands are transmitted to ROV through an umbilical cable. ROV makes corresponding actions according to the command.

Data collected by the camera and various sensors are also transmitted to the deck unit through an umbilical cable. The umbilical cable, which is a zero-buoyancy cable with certain strength, can guarantee the normal deployment and recovery of ROV. The specific structure of the system is shown in Fig. 3.

The ROV system is composed of seven main parts: main frame, floating material, control communication system, power propulsion system, observation and lighting system, manipulator system, and sensor detection system (Guan 2018).

- *Main frame*: The main frame is the carrier of the entire ROV system and its reasonable structural design based on the overall size of the ROV. The main frame should be firm and stable.
- *Floating material*: The common floating materials utilized in underwater vehicles are polymer-based solid material, which is characterized by low density (0.2 to 0.7 g/cm^3), low water absorption (less than 3%), high mechanical strength (e.g., compression strength is in the range of 1 to 100 MPa), corrosion resistance, and machinability. Polymer-based solid material could meet various requirements in the underwater environment. It is noted that floating body materials should be selected according to the maximum water depth.
- *Control communication system*: The control communication system is a comprehensive system, which includes collecting, transmitting, processing, and analyzing various information and commands of the ROV. The control system transmits real-time control commands to the ROV through the umbilical cable, and thus the ROV is controlled to perform some specified work tasks. At the same time, the information such as ROV's depth, attitude, and image is transmitted to the deck unit in real time through the umbilical cable for analysis and processing.
- *Power propulsion system*: The power propulsion system mainly includes two parts, the thruster and the power supply. The power propulsion system supports the mother ship deck to provide power to the ROV through

Remotely Operated Vehicle (ROV) in Subsea Engineering, Fig. 3 Block diagram of ROV system

- the umbilical cable and drives the thruster to achieve the command-controlled ROV movement.
- *Observation and lighting system:* The observation and lighting system are mainly composed of cameras, sonars, and LED lights. ROV can obtain underwater image through the observation and lighting system, which contributes to ROV in avoiding obstacles, improving the efficiency and safety during operation.
 - *Manipulator system:* The manipulator system is the key symbol of ROV’s operating capability, which is an indispensable part in an operating-oriented ROV. The manipulator system is mainly composed of a manipulator, a hydraulic pump, and a control valve. The manipulator has lots of basic parameters, among which the degrees of freedom,

movement space, load capacity, and selection of materials are important parameters for its design. During operating, the operator sends control signals from the control box on the deck of the mother ship, and the control signals are transmitted to the underwater control system through the umbilical cable, which controls the manipulator to complete certain tasks.

- *Sensor detection system:* Sensor detection systems mainly include altimeters, pressure sensors, attitude sensors, temperature sensors, ultrashort baselines, and cable detection sensors. Various underwater detection information collected by the sensors is transmitted to the deck unit through the umbilical cable. Based on the information, the operator analyzes and judges the status of the ROV, which is beneficial to achieve the ROV operation control.

ROV System Design

Overall Structural Design

In designing ROV, the engineers should make clear the design goal, the operation task, the working mode, and the working environment. The mature ROV technology in worldwide can be referenced in the design of overall structure framework. The ROV body is discretized into several blocks for modular design. The connection among different modules should be concerned during module design, in order to maintain the integration of each module. Some aspects should be carefully considered in the over structural design of ROV.

- Compact layout. The limited space in the ROV should be fully used without interference among each part of the ROV. The overall size of the ROV should be optimized for convenient transport and storage.
- The technical performance and requirements for the working environment of ROV should be fully taken into consideration, which ensures the normal use of the equipment and avoid interference with each other.
- Without interfere normal function, the design of the components and the connection among the modules should be simplified in maximum extent, which is beneficial to facilitate the maintenance of the ROV.
- Under full consideration of operational requirements, sufficient spare space should be

reserved for ROV system updating and modifications.

- The durability, reliability, and stability of control systems and mechanical components in ROV must be ensured.

Design of ROV Propulsion System

The thruster is the main power source for the ROV. There are many kinds of thrusters, among which the propeller thrusters are widest utilized. The number of degrees of freedom of ROV in underwater movement is determined by the operation purpose and design requirement. Three degrees of freedom, i.e., forward and backward, up and down, and steering, are the basic mobility requirements of a ROV. The number of thrusters required for ROV is determined by the purpose and design requirements.

At present, the layout of thrusters can be divided into five types: single thruster layout, parallel layout of double thrusters, cross layout of double thrusters, annular layout of four thrusters, and conical layout, as shown in Figs. 4, 5, 6, 7, and 8.

For arranging thrusters, two points should be paid attention:

- The axis should be parallel to the moving coordinate system, which maximizes the efficiency of the thruster.
- The axis of three-axis thruster should be reasonably converged to one point. This point

Remotely Operated Vehicle (ROV) in Subsea Engineering, Fig. 4 Single-pusher arrangement

Remotely Operated Vehicle (ROV) in Subsea Engineering, Fig. 5 Parallel arrangement of dual thrusters

Remotely Operated Vehicle (ROV) in Subsea Engineering, Fig. 6 Double-thruster cross arrangement

Remotely Operated Vehicle (ROV) in Subsea Engineering, Fig. 7 Ring arrangement of four pushers

should approach to the center of gravity of ROV in order to avoid some harmful movements of ROV and benefit to the system control.

Overall Balance Design
Due to many equipment on ROV, the weight symmetry of ROV should be taken into consideration, in order to maintain the gravity position and

Remotely Operated Vehicle (ROV) in Subsea Engineering, Fig. 8 Cone arrangement of thrusters

the metacentric position. In practical, it is very difficult to achieve the absolute balance of ROV. Therefore, the arrangement of ROV's internal equipment should follow some principles:

- The primary body should be firstly considered and then other parts.
- The global layout should be firstly considered and then local arrangement.
- Some certain amount of space should be left, which leaves the room for modification.

In order to ensure the stable motion of ROV, a certain stable height should be guaranteed. The metacentric height of general underwater vehicles should be greater than 7 cm, and the metacentric height of large underwater vehicles should be correspondingly increased. In order to determine the metacentric height, the coordinates of center of gravity and center of buoyancy need to be calculated according to the overall arrangement of ROV. Besides, the coordinates of center of gravity and center of buoyancy of ROV can also be calculated in 3D drawing software. It is necessary to ensure that the line between the barycentric coordinates and the center of buoyancy coordinates passes vertically through the underwater vehicle so that no overturning moment occurs when it is stationary. Otherwise, the general layout of ROV should be adjusted so that the two coordinate positions are equal as far as possible; even if they are not absolutely equal, the angle formed between the two

coordinate lines and the vertical line should be kept within the range of 0 to 15°.

Dynamic Analysis of ROV

For studying the motion law of ROV, its kinematic and dynamic modeling should be developed. Kinematics describes the relationship between location and time, while dynamics focus on the relationship between force and motion (Liu et al. 2015).

Force Analysis of ROV in Water

ROV is mainly affected by buoyancy, gravity, thrust of thrusters, hydrodynamic and umbilical cable interference forces, and the torque generated by these forces during underwater movement. The combined force and moment formed by these forces and moments make the ROV produce six degrees of freedom in space motion.

Gravity and Buoyancy: The buoyancy and gravity of ROV are always in the vertical direction. Gravity is represented by P , and buoyancy is represented by B . The gravity center is represented by G , and floating center is represented by C . It is assumed that the coordinates of the center of gravity and the floating center in the x and y directions are coincident (which can be achieved by balancing the weight and buoyancy), and the floating center is higher than the center of gravity in terms of h . Without considering the changes of buoyancy and load, the components of gravity, buoyancy, and moments

on the axes of the ground coordinate system can be calculated by corresponding formulas.

Thrust of the Thruster: The thrust generated by the propeller is the power that enables the ROVs to move in their respective degrees of freedom. The thrust generated by the propeller can be calculated from the propeller thrust formula.

Water Resistance: In underwater environment, the resistance of ROV mainly consists of two parts: the hydrodynamic force and the interference of the umbilical cable. The calculation of hydrodynamics is complex. There are around 100 parameters relative to hydrodynamic coefficient. Generally, the hydrodynamics is related to the geometry, motion state, and flow field properties of a ROV (Liu et al. 2020).

The calculation of the umbilical cable's interference force is also complex. Generally, it can be calculated by the concentrated mass method, that is, the umbilical cable is regarded as a chain model. In a chain model, the umbilical cable is assumed as a chain including a series of cylinders with finite length and concentrated mass at one point. According to the movement status of the mother ship and ROV, mechanical analysis and calculation are performed on each section of umbilical cable, and then the interference force of umbilical cable on ROV can be obtained.

In practical, an approximate estimation method can generally be used to calculate the resistance force of ROV in underwater environment. The resistance to which it is subjected can be estimated by the resistance formula (Fan et al. 2012).

ROV Dynamic Modeling and Analysis

According to rigid body dynamics theory and Newton-Euler equation, the six-degrees-of-freedom equation of ROV is obtained, and then the dynamic equation is established by combining the four forces of gravity, buoyancy, propeller thrust, and water resistance (Nakamura et al. 2013). The motion posture of ROV corresponding to the next moment can be calculated from the motion posture and external force of the previous moment, which is an indispensable basis for ROV motion control.

In order to verify the dynamic effect of ROV, CFD simulation method is often used (Yan et al.

2010). This method uses computer as the tool, uses discrete mathematical method, and uses simulation software to simulate and analyze the mathematical model.

ROV Control System

The control system is the core of the ROV, which mainly includes the hardware system and the software system. The hardware system is divided into two parts, the surface control system and the underwater control system. The software system is divided into two parts, an operation part and a monitoring part. The surface control system is responsible for collecting ROV's control instructions, including digital quantities and analog quantities. The underwater control system is responsible for responding to the control instructions of the surface control system and also feeding back the corresponding status and data in real time. The software system is responsible for sending operation instructions and receiving and processing data. The cooperation of the hardware system and the software system can ensure the normal operation of the ROV. The overall block diagram of the ROV control system is shown in Fig. 9.

ROV Control Hardware System

The overall system of ROV is complex and it involves many control targets. A large number of sensors and equipment are involved in its control system. Due to the difference among electrical interfaces and communication protocols, there still are different communication rates and specifications, even though the same the electrical standards are utilized. Hence, the integration of various interface standards and flexible configuration modes are compulsory in the design of the ROV's control system. Moreover, some certain degree of redundancy should be considered for later maintenance, expansion, and upgrade.

Common ROV underwater main control units are as follows:

- Based on the main control method of PC104. RS232, RS485, AI (analog input), DI (digital

Remotely Operated Vehicle (ROV) in Subsea Engineering, Fig. 9 ROV overall control system block diagram

input), Ethernet and other modules are configured on the interface, which are operated by Windows or Linux system.

- Based on embedded systems of single-chip microcomputers. RAM-based embedded hardware is commonly used, which is operated by Linux, uCOSII, and other operating systems, or without an operating system directly.
- Based on the PLC of the industrial automation industry, various common interface modules can be configured according to the ROV. Depending on different PLCs, the manufacturer can develop the operating system or use the general operating system.

ROV Control Software System

The ROV control software system is the core part of the ROV control system. The ROV control software system contains an operation part and a monitoring part. The operation part is the fundamental software, which is responsible for identifying the information of the joystick and operation buttons and communicating with the ROV in real time. Its software interface mainly completes the following functions:

- Configure the initialization information of the ROV software.
- Configure the initialization information of each sensor, such as communication mode, communication rate and so on.
- Control the enable status of the thruster and monitor the thruster speed.

- Feedback the current speed of ROV's movement in real time.
- Feedback the current depth of the ROV in real time, and estimate the ROV dive speed and dive time.
- Feedback the current ROV off-bottom height in real time, combined with the depth parameter of the ROV, and control the ROV movement speed.
- Real-time feedback of ROV electronic cabin temperature and monitoring of the operating system temperature of the electronic system.
- Real-time feedback of ROV water leakage detection status and monitoring the pressure-tight status and waterproof status of the electronic cabin.
- Feedback the status of underwater lights and cameras in real time, and check whether they are turned on correctly.
- Feedback the operating status of the manipulator in real time, and compare it with video monitoring to ensure the correct operation of the manipulator.
- Detect the hydraulic pump pressure in real time to ensure the correct operation of the manipulator, and eliminate errors.
- Configure an appropriate debugging window to detect PLC and other internal variables, and troubleshoot the failure rapidly.

ROV Motion Control Method

The main parameters of ROV motion control are depth (the vertical distance from the sea surface to

the center of gravity of the underwater vehicle), height (the vertical distance from the seafloor to the center of gravity of the underwater vehicle), heading angle, speed, position, and so on. In most ROV designs, in order to obtain good control performances without complicating the system, single-loop closed-loop control is used for these parameters, such as depth loop (auto-depth control), altitude loop (auto-height control), heading angle loop (auto-heading control), speed loop (constant speed control), position loop (automatic positioning), etc.

On the basis of the basic circuit of the motion control system, a certain control algorithm is also needed to achieve accurate control of the motion of the underwater vehicle. The common control algorithms include PID control, fuzzy control, adaptive control, and neural network control.

Sensing and Communication System in ROV

Common Sensor Used in ROV

There are three main sensors used in ROVs, navigation and positioning sensors, operating system sensors, and condition monitoring sensors.

Navigation and positioning sensors: Navigation and positioning system sensors include depth sensors, gyroscopes, Doppler Velocity Logs, acoustic positioning systems, inertial navigation systems, imaging sonars, etc. The function of navigation and positioning system sensors is collecting information on the position, attitude, and speed of the underwater vehicle in the water and detecting the vehicle's surroundings. The specific functions of each sensor are described as follows:

- Depth sensor: Measure the water depth in respect to vehicle's position.
- Altimeter: Measure the distance between vehicle and sea floor.
- Gyroscope: Measure the attitude of the vehicle in the water.
- Doppler log (DVL): The Doppler log is used to determine the speed of an underwater vehicle relative to the ocean floor.

- Acoustic positioning system: Acoustic positioning system is a technology that uses underwater acoustic equipment to determine the position and distance of the vehicle relative to the mother ship.
- Inertial navigation system: The inertial navigation system consists of a gyroscope and an accelerometer. By measuring and integrating the ROV's angular velocity and acceleration, the ROV's speed, yaw angle, and position in the navigation coordinate system can be obtained.
- Imaging sonar: Imaging sonar is an acoustic device whose principle is similarly to a radar. The sonar transducer, equivalent to a radar antenna, can emit sound waves and receive sound waves reflected from the surrounding environment and then produce acoustic images of the surrounding environment.

Operating system sensors: Operating system sensors refer to the various sensors that ROVs carry when operating underwater. Different operating systems use different sensors, including electromagnetic detection sensors and acoustic detection sensors.

Condition monitoring sensor: To ensure the safety of the ROV system, some sensors are needed to monitor the vehicle. For example, the battery voltage and power detection sensors can reflect the battery usage; the water leakage detection sensors in the sealed cabin can detect the sealing performance of the sealed cabin in real time.

Communication Technology

The core of the ROV communication system is data exchange between the aquatic equipment and the underwater equipment through a cable. The common methods are optical fiber communication and power line communication.

Optical fiber communication: A communication method that uses light waves as a carrier wave and uses optical fiber as a transmission medium to transfer information from one place to another is called *wired* optical communication. At present, optical fiber has been widely used in the communication system of underwater vehicles due to its

transmission frequency bandwidth, long transmission distance, high interference resistance, and small signal attenuation.

The principle of ROV optical fiber communication is as follows: the transmitted information (such as sensor data and video shot by an underwater camera) is firstly converted into an electrical signal at the transmitting terminal. Then it is modulated onto the laser beam emitted by the laser, so that the intensity of the light varies with the amplitude (frequency) of electrical signal. By transmitted through the optical fiber, the detector converts the optical signal into an electrical signal at the receiving end and restores the original information display after demodulation.

Power line communication: The use of power carrier communication in the ROV communication can combine the power supply line and the signal transmission line, which can reduce the number of cores in the zero-buoyancy cable. The principle of the power carrier in ROV is the following: the transmitted information is modulated onto the power line through the carrier module. After the power line transmission, it is demodulated on the carrier module at the other end to obtain the transmitted information.

Acoustic communication: Affected by seawater, electromagnetic waves diminish rapidly, and they cannot be used as a technical method for long-distance communication, while light waves are affected by the turbidity, absorption, and scattering in the water (Yong and Weigang 2019). Relying on current technology, only stable connections can be achieved over short distances. The propagation speed is fast; although it is affected by the noise, it can realize long-distance communication through filtering. The acoustic communication has stable and reliable applications on the *Jiao Long* and *Deep Sea Warrior* deep submersibles. It is assumed as one of the most promising directions in the development of acoustic communication in the future.

Conclusion and Prospect

Most underwater vehicles now have a certain degree of motion flexibility and superior navigation,

imaging, and sensing capabilities; however, they are still not reliable enough to integrate with marine life and to deal with unknown problems. Some challenges are still faced, including underwater communication, positioning measurement, mid-deep navigation, and unpredictable interference. With the continuous expansion of the application field, the underwater vehicle will develop toward smaller size, more compatibility, and higher intelligence, in order to break through the obstacles in the design of unmanned underwater vehicle, which may greatly improve its automation; in addition, some new technologies (e.g., multimedia technology and virtual reality technology) should be applied to underwater vehicles for future development.

Rescue Bell

Yong Hu

Shanghai Jiaotong University, ShangHai, China
School of Transportation, Wuhan University of Technology, Wuhan, China

Synonyms

Rescue chamber; Submarine rescue bell

Definition

Rescue Bell is one type of submarine rescue system, which can carry submariners from a disabled submarine to the surface. A typical Rescue Bell consists of four major components: a pressure hull, mating skirt, surface support system, and life support system. Some rescue bells also have propellers, imaging system.

Scientific Fundamentals

Historical Development

During the first two decades of last century, in the United States Navy Submarine Force, there were several accidents in which Navy submarines sank with the loss of life. These experiences led submariner Charles B. Swede Momsen to think of technical alternatives for rescuing survivors

from sunken submarines, which at that time was still a virtual impossibility. Momsen soon conceived a submarine rescue chamber that could be lowered from the surface to mate with a submarine's escape hatch and proposed the concept through official channels. While in command of the submarine S-1 (SS-105), in 1926, Momsen wrote to the Bureau of Construction and Repair (BuC&R) recommending the adoption of a diving bell for the purpose of rescuing entrapped personnel from submarines. But this idea was pigeonholed by the bureaucracy, even during his own subsequent assignment at BuC&R. The loss of S-4 with all hands put the Navy very much "on the spot" because of the loss of lives that might have been saved. The pressure of this incident forced favorable action and Momsen, using the aircraft hangar from S-1, designed and built a prototype submarine rescue chamber (Fig. 1).

Rescue Bell, Fig. 1 Momsen-McCann rescue bell prototype

During the first 3 months of 1928, divers and other salvage personnel were able to raise S-4 and tow her to the Boston Navy Yard, where she was drydocked and repaired. She returned to active duty in October 1928 and was employed thereafter as a submarine rescue and salvage test ship. Momsen went to sea in the reconditioned S-4 to carry out practical experiments and training with the rescue chambers.

Work with S-4 helped to develop equipment and techniques that bore fruit a decade later, when 33 men were brought up alive from the sunken submarine *Squalus*. The first diving bells for rescuing men from submarines were designed by the BuC&R in 1928. The diving bell went through a series of tests off the shores of Key West, Florida. Based on these tests, Momsen had several changes in mind for the bell, and after nearly 2 years of experimentation full of highly interesting results, the final bell was evolved and christened a "rescue chamber." This success was catalyst for gaining approval for the development of the submarine rescue chamber in 1930.

Lieutenant Commander Allan Rockwell McCann was put in charge of the revisions on the diving bell. From July 1929 to July 1931, McCann was assigned to the Maintenance Division, Bureau of Construction and Repair, where he developed the submarine rescue chamber. When the bell was completed in late 1930, it was produced as the McCann Submarine Rescue Chamber (SRC) (Navy designated the first 12 of these as YRC 1-12, YRC-4 was lost aboard the USS *Pigeon*, at Bataan, Philippines during the first days of WWII. YRC-5 was aboard the USS *Widgeon* (AM-22) during the Pearl Harbor attack). In 1931, a one-fifth scale model of a diving bell for submarine rescue work was built and tested. Design called for the bell to withstand the external pressure encountered at a depth of at least 300 ft (91 m) of water, and the test showed the model fulfilled this requirement with a factor of safety of about 3.5. The vessel was tested under external pressure, failure occurring in the shell at a pressure of 470 psi (3,200 kPa). Since the head of the vessel remained intact, it was decided to make a test of the head itself in order to determine its strength relative to that

of the shell, and if possible to obtain some measure of the stresses occurring under load. The head collapsed at a pressure of 525 psi (3,620 kPa), indicating its strength under external pressure was about 10% in excess of that of the shell.

The revised Submarine Rescue Chamber had improvements including a soft seal gasket for sealing the submarine/bell interface skirting, and a floor installed to maintain air-space in the bell during raising and lowering. Momsen in his speech to the Harvard Engineering Society on 6 October 1939 credits Allan Rockwell McCann with the improvements which made the bell operational, safe, and large enough to hold up to eight rescued crewmen and two operators.

After the development of the rescue bell, the US Navy was equipped with dozens of rescue bell. After 1970s, the Deep Submergence Rescue Vehicle (DSRV) replaced the rescue bell.

In recent years, China continues to develop the modern rescue bell. China has developed a type of movable rescue bell in 1990s successfully. This type of rescue bell has four thrusters. This rescue bell has better mating ability than McCann rescue bell. The working depth of the movable rescue bell is 200 m. The bell has umbilical line for power supply, with a rotary skirt. The mating angle can reach 20°. McCann rescue bell is a simple rescue chamber. Chinese rescue bell has the ability of manned occupied submersible, but the rescue principle is the same as McCann rescue chamber (Fig. 2).

In 2008, China has successfully developed a new type of rescue bell, Maneuvering Rescue Bell. The maneuvering rescue bell has a 45° rotary skirt. The rescue bell can be carried by truck, train, or airplane. The high-pressure seawater pump can drain off the skirt water quickly. The energy supply comes from the mother ship, and the rescue bell can work continuously (Fig. 3).

Key Technology in the Development of a Rescue Bell

In the development of the modern rescue bell, mating skirt and life support system are the key technology. Most equipments are the same as human occupied vehicle and ROV. For the mating skirt, big mating angle, light weight, and reliable

Rescue Bell, Fig. 2 China
movable rescue bell

Rescue Bell, Fig. 3 China
maneuvering rescue bell

R

sealing are the key technical specifications. For the life support system, rescue with pressure is a complicated rescue condition. Under this condition, mating and transfer are very difficult. And the life support system can support the rescuer under high air pressured environment.

The McCann bell suffers from severe limitations in strong currents and when dealing with a pressurized submarine or one lying at extreme

angles. The Rescue Chamber is air transportable to a Vessel of Opportunity (VOO) Mother Ship (MOSHIP), which requires little modification to use the system. Transfer Under Pressure (TUP) to and from pressurized environments such as submarines or hyperbaric chambers is not possible with this system, even though TUP is essential where being subjected to ambient pressure may be life-threatening.

The modern rescue bell such as the movable rescue bell and the Maneuvering Rescue Bell can deal with 2.5 knots currents. The extreme angle can reach 45°. The modern rescue bell can mate and rescue at pressurized environments under 50 bars.

Key Applications

In 1939, the McCann Rescue Chamber made its debut when it was used to successfully rescue 33 survivors from Squalus. At the time of Squalus' accident, Lieutenant Commander Momsen was serving as head of the Experimental Diving Unit at the Washington Navy Yard. The submarine rescue ship USS Falcon (ASR-2), commanded by Lieutenant George A. Sharp, was on site within 24 h. It lowered the Rescue Chamber, a revised version of a diving bell invented by Momsen and, in four dives over the next 13 h, recovered all 33 survivors in the first deep submarine rescue ever. McCann was in charge of Chamber operations, Momsen commanding the divers. Although there was no reason to believe anyone was alive in the aft part of the ship, a fifth dive was made to the aft torpedo room hatch on May 25. This run confirmed the flooding of the entire aft portion of the ship.

Although there are no other actual rescue cases, the Chinese navy carries out rescue training every year. The training includes mating and rescue submariner testing through actual submarine. Due to the low cost and simple rescue procedures, the rescue bell is still a simple and efficient submarine rescue equipment.

Definition

A research ship is a special ship or boat designed, modified, and equipped to carry out research at sea, which is carrying scientists and special equipment. Research ships are applied in marine natural science research such as geology, geophysics,

hydrology, meteorology, chemistry, biology, landforms, and so on.

Scientific Fundamentals

Development History

On the basis of great technological changes and typical characteristics of ship types, there are two main periods in the development history of the world research ships (Wu 2017).

First Development Period

The first development period of research ships is from the late 1950s to 1980s. Along with the application of electronic computers and the emergence of various kinds of advanced marine survey equipment, modern research ships are built gradually. Compared with the early refitted research ships, research ships in the first generation have qualitative improvements in performance, laboratories and special equipment, etc. (Griffin and Sharkey 1987).

There are a series of research ships that are built in the first development period, such as the 6000 t comprehensive research ship “Romenosov” built in the Soviet Union in 1959, the 3400 t hydrographic research ship “Surveyor” built in the United States in 1960, the research ship “ATLANTIS II” built in the United States in 1962, the 3100 t research ship “DISCOVERY” built in the British in 1962, the 4700 t reconstructive research ship “SONNE” built in Germany in 1977, etc.

The first reconstructively comprehensive research ship “Venus” is the pioneer of marine research ships in China in 1956 (Zhang 1998). Since that, there are typically representative research ships, such as the first meteorological research ship “Qixiang 1” designed and built independently in 1959, the comprehensive research ship “Dongfanghong” built in 1965, the 3000 t comprehensive research ship “Shijian” built in 1969, the 4400 t comprehensive research ship “Xiangyanghong 09” built in 1978, the ton class comprehensive research ship “Xiangyanghong 10” built in 1979, the 3000 t geological research ship “Haiyangsihao” built in 1980, the 3300 t

comprehensive research ships “Kexue 1” and “Shiyan 3” built in 1980, etc.

There are a few function shortages of research ships in this period (Li 1982). Loud noise and big vibration can’t meet the demand of acoustic experiment research. Survey equipment and laboratories are outmoded and defective. Besides, outdated detection method and small detecting depth and range are difficult to realize multidisciplinary research. And data transmission and processing are unable to complete in the field. What’s more, high speed results in wasting energy.

Second Development Period

The second development period of research ships is since the late 1980s. As the gradual improvement of the electric propulsion system and the dynamic positioning system, as well as a variety of upgraded research equipment, the design of research ships is more and more automatic and modularized (European science foundation 2009; Zhu et al. 2012). Therefore a series of new advanced research ships replace the overage ships.

There are a series of typical research ships in the period, such as the 18,000 t ocean drilling ship “JOIDES” built in the United States in 1984; the 3600 t “Atlantis III” built in the United States in 1997, which is the mother ship of Alvin DSV (Deep Sea Vehicle); the 6300 t ice comprehensive research ship “Maria S. Merian” built in Germany in 2006; the 3000 t comprehensive research ship “Sarmiento de Gamboa” built in Spain in 2007; the 5800 t comprehensive vessel “JAMES COOK” built in the British in 2007; the 57,000 t ocean drilling ship “CHIKYU” built in Japan in 2007; the icebreaker polar research ship “Akademik Tryoshnikov” built in Russia in 2012; the 6000 t new “DISCOVERY” built in the British in 2013; the 3200 t comprehensive survey ships “AGOR 27” and “AGOR 28” built in the United States in 2014; the 6000 t comprehensive survey ship “Investigator” built in Australia in 2014; the 8000 t new “SONNE” built in Germany in 2015; etc.

The building of Chinese research ships appears a little delayed from the middle 1980s to the end of the twentieth century (Li et al. 2012). After the

research ship “Dongfanghong 2” designed and built independently, the modified ships “Dayang 1” and “Snow Dragon,” and so on, the marine survey in China begins into the deep sea and the polar area. But the limited number of ships is not content with the actual demand of the development of marine survey in China. It enters into the peak development of research ships since the twenty-first century. There are, respectively, advanced research ships such as “Shiyan 1,” “Haiyangliuhao,” “Kexue,” “Xiangyanghong 10,” “Xiangyanghong 03,” “Xiangyanghong 01,” “Zhangjian,” “Jiageng,” etc.

Basic Type

Different countries have different strategic target, research area, foundation of parent ships, as well as capability of design and production. According to the characteristics and functional requirements of research ships, there are different classification methods (Meng et al. 2017; Wu 2017). Forms of research ships include mono-hull, catamaran, and special hull. According to the gradation standard of the US Federal Oceanographic Facilities Commission (shown in Table 1, FOFC 2001), gradations of research ships include global class, ocean class, regional class, and coastal class based on the ability of navigation and operation. Based on research tasks, they are divided into comprehensive research ships, subject research ships, and special research ships. However, common subject research ships are geophysical survey ships, geological survey ships, acoustic research ships, fishery research ships, meteorological research ships, environmental surveillance ships, buoy receive and release ships, etc. And special research ships are oceanographic drilling ships, polar research ships, space tracking ships, submersible carriers, archaeology ships, etc.

Comprehensive research ships regard multiple marine subjects and research fields as survey objective. They possess comprehensive survey capability of various functions and techniques. They can conduct marine geology, geophysics, geochemistry, biology, hydrometeorology, hydroacoustics, and fisheries and other marine survey. They can carry out comprehensive research from the upper atmosphere to the seabed through the air-sea interface. They mostly work in the ocean near their own sea or further area. Generally speaking, comprehensive research ships have more form values, cruising ability and self-supportability, and better properties, along with more complete survey equipment.

Fishery research ships are engaged in the scientific research of fishery resources and fishing ground environment, the experimental study of fishing gears and fishing methods, etc. They are capable of towing different types of fishing nets, collecting plankton or water samples, and carrying fish-finders. A fishery research ship is often designed and built along the same lines as a large fishing vessel, but with space given over to laboratories and equipment storage, as opposed to storage of the catch.

Geology research ships are applied in the research of marine geology, geophysics, and geothermics, by the means of seismic, gravity, and magnetic survey and sampling analysis. These studies can obtain the sedimentary and structure of seabed and make further information of the seabed mineral resources. These ships are equipped with special survey equipment as well as laboratories.

Oceanographic drilling ships can drill core samples of the seabed and obtain chemical and biological information of them. These ships are equipped with tall derricks, heavy lifting

Research Ship, Table 1 Gradation standard of research ships (FOFC 2001)

Gradation	Length/meters	Self-supportability/days	Endurance/nautical miles	Personnel
Global class	70	50	13,500	30–35
Ocean class	55–70	40	10,800	20–25
Regional class	40–55	30	8100	15–20
Coastal class	<40	<20	<5400	<15

equipment, and a full set of core sampling system, especially dynamic positioning system which can maintain a fixed position.

Acoustic research ships can conduct marine acoustic information acquisition for underwater acoustic intercept and acoustic research. Meanwhile, this information is applied in military affairs such as underwater target alert. Professional acoustic research ships must have lower noise and less vibration in order to satisfy the normal use of acoustic equipment.

Polar research ships are applied to investigate the polar information, such as hydrology, meteorology, and biology. They are constructed around an icebreaker hull, allowing them to engage in ice navigation and operate in polar waters. These ships usually have dual roles, particularly in the Antarctic, as polar replenishment vessels to the Antarctic research bases. Due to the specificity of working areas, polar research ships must have solid structure and larger values to support polar working for a long time.

Hydrographic research ships are designed to conduct hydrographic research and survey. Nautical charts are produced from this information to ensure safe navigation by military and civilian shipping. These ships usually mount equipment on a towed structure, for example, air cannons, used to generate a high-pressure shock wave to sound the strata beneath the seabed. This information is useful for detecting geological features which are likely to bear oil or gas. Naval hydrographic research ships often do naval research, for example, on submarine detection.

Key Technology

Comparing with regular ships, research ships have some specific technical requirements according to the demand of survey tasks.

Dynamic positioning system can propel and adjust the position of ships with sensors and thrusters automatically (Li 2014). Precise dynamic positioning system plays an important role in the operation process, such as clothing and recycling of survey equipment, as well as bottom sediment sampling (Zhang et al. 2015). In general, research ships are required to hold a

certain position and course, which are not far from a predesignated position.

Good maneuverability and steady slow propulsion performance are also important. The economical speed of research ships is 12–15 knots, while holding a low speed of 3–6 knots for a long time is necessary for measurement and trawling operation. Controllable pitch propellers, electric propulsion, and thruster systems can effectively realize slow sailing (Li 2014). To improve the maneuverability of research ships, they are always equipped with bow thrusters and stern thrusters, as well as active rudders.

In order to improve measurement accuracy, low noise and little vibration are necessary that strong hull can ensure low noise and little vibration of research ships. That is to say, they require good stability and surge immunity. It is effective to reduce noise and vibration by form and structure design of research ship as far as possible. Besides, advanced research ships are equipped with anti-rolling tank to reduce the freeboard and windward area.

Besides, research ships must have enough power load and electromagnetic compatibility. Certain redundancy and enough power load of the power station are necessary to guarantee the normal operation of different types of professional survey equipment. Instrument electricity must be separate from dynamics electricity and living electricity (Wu 2018). All electronic systems are mutually compatible and noninterfering to reduce and eliminate the electromagnetic interference. It is very important for ensuring security of the personnel and equipment on the research ship. In addition, acoustic research ships still need to set up undisturbed power supply.

In addition, deck area and laboratory area are the main workspace of field science research. Enough deck area can match the storage, fixation, and operation of different sizes of equipment, especially in a large comprehensive survey voyage. Laboratory area is generally divided into different cabins, such as universal dry or wet laboratory, thermostatic laboratory, chemical laboratory, data processing room, equipment room, sample storeroom, and so on. Laboratory

modularization becomes a development tendency of the design of research ships (Zhang et al. 2015).

Survey Equipment

The equipment of modern marine research ship consists of two parts, the operating control system and science survey equipment (Li et al. 2017).

Operating Control System

The operating control system referred to all the auxiliary equipment that support various research, including winch system, lifting system, air compressors, shipping network system, etc. The winch system generally includes conductivity, temperature, and depth (CTD) winches, optical-fiber cable winches, coaxial cable winches, steel rope winches, etc. Lifting and retraction system includes tail A frames, side A frames, flexible knuckle cranes, telescopic spreaders, etc. Air compressors provide compressed air for multiple seismic detection system. Shipping network system can carry out data management, ship management, web portal management, and so on.

Science Survey Equipment

Science survey equipment mainly includes underwater detection system, atmospheric sounding system, submarine exploration system, remote sensing information field verification system, and so on.

Underwater detection system is applied in comprehensive exploration of three-dimensional distribution features of marine hydrological, acoustic, chemical, and biological elements. We can study ocean circulation dynamic process, the distribution of fishery resources, and the regularity of marine acoustic propagation. The representative equipment includes conductivity, temperature, and depth (CTD), acoustic Doppler current profilers (ADCP), acoustic wave recorders, current meters, salinity meters, sound velocity profiler (SVP), fish-finders, wave buoys, underwater gliders, biological layered continuous sampling system, etc.

Atmospheric sounding system allows obtaining continuous real-time meteorological information to study three-dimensional air-sea

interaction and atmospheric sciences. The detecting equipment includes air-sea boundary layer observation system, shipborne automatic meteorological stations, aerosol time-of-flight mass spectrometer (ATOFMS), CO₂ measurement system, etc.

In addition, submarine exploration system is applied to detect the surface and formation of the seabed and then explore the sedimentary environment, geologic structural setting, and mineral resources below the seafloor. Common equipment includes multi-beam submarine geomorphic detection system, single-beam or multi-beam depth finders, sub-bottom profilers, marine gravimeters, marine magnetometers, submarine in situ observation system, multiple seismic detection system, deep-sea towing system, heat flow probes, side-scan sonar system, geological drilling sampling equipment, cone penetration test (CPT), underwater camera system, etc.

Furthermore, remote sensing information field verification system can obtain high-quality seawater information providing spot calibration and algorithm verification of satellite ocean remote sensing. The representative equipment includes waves and surface current detection system, underwater multispectral absorption and attenuation measuring instrument, offshore or underwater hyperspectral radiation measuring instrument, etc.

Key Applications

American Polar Research Ship “Sikuliaq”

“Sikuliaq” is an American polar research ship owned by the National Science Foundation and operated by the University of Alaska Fairbanks School, built in 2014 (shown in Fig. 1) (Sun and Liu 2018). The major research tasks include the effect of climate change and increased human use of Arctic regions on various issues such as ocean circulation and ecosystem dynamics.

It has a length of 79.6 m, a width of 15.85 m, a depth of 8.5 m, a draft of 5.715 m, a displacement of 3724 t, and a maximum speed of 14.2 kn. It can sail 18,000 nm at 10 kn. The ice class is Polar Class 5. It can break 1st-year sea ice up to 0.76 m

Research Ship,

Fig. 1 American polar research ship “Sikuliaq” (<https://www.wikipedia.org/>)

thick at a constant speed of 2 kn, which inspired her name. One of the most advanced research vessels ever built, it has extensive scientific facilities. In addition to 209 m² of built-in laboratories, it can accommodate two to four 20 ft scientific containers on the 405 m² aft deck. Designed for operations in ice-infested waters, it has a sloping icebreaker bow and a hull that is 2 ft wider at the bow than in the stern to reduce ice resistance. Besides, it also has dynamic positioning capability. It is equipped with diesel-electric propulsion system, powered by four MTU 4000 series high-speed diesel engines. It is one of the first vessels ever to be fitted with Icepod propulsion units, Wartsila brand of ice-strengthened azimuth thrusters that can be rotated 360° about the vertical axis. It is also fitted with a bow thruster to assist maneuvering at low speeds.

Chinese Polar Research Ship “Xue Long 2”

“Xue Long 2” is the first polar research ship constructed by China, scheduled to enter service in 2019 (shown in Fig. 2) (Xinhua Net 2017). She will serve both as a supply vessel for China’s research facilities in the Arctic and Antarctic regions and as a research vessel, with capabilities for geological and biological experimentation and surveying.

She measures 122.5 m long, with a beam of 22.3 m and a draft of 8.3 m at full load. She has a

displacement of 14,300 t. She has a diesel-electric propulsion system, with two 16-cylinder and two 12-cylinder engines, both Wartsila 32-series designs, powering two 7.5 MW Azipods that give her a speed of up to 15 kn in open water and 3 kn when breaking ice. She is classed as a PC3 icebreaker under the Polar Class of measurement and is able to break ice up to 1.5 m thick while traveling either ahead or astern. In addition, all of the generators are equipped with exhaust gas cleaning system to protect polar environment.

Japanese Ocean Drilling Ship “CHIKYU”

The largest ocean drilling ship in the world “CHIKYU” is a member of Japan Marine Association, built by Mitsubishi Heavy Industries shown in (Fig. 3) (Shen 2011). It has a length of 210 m, a width of 38 m, a depth of 16.2 m, a height of 130 m, a draft of 9.2 m, a displacement of 56,752 t, cruising ability of 14,800 nm under 10 kn, and a maximum speed of 12 kn. It can accommodate 200 passengers at a time.

The biggest feature is a huge riser drilling rig rising 121 m above sea level. It is capable of drilling 7000 m into the ocean floor in deep sea areas with a water depth 4000 m. It is equipped with six diesel generators with a total power of 35,000 kW, one 2550 kW bow thruster, and three 4100 kW azimuth thrusters and three same

Research Ship,

**Research Ship,**

Fig. 3 Japanese ocean drilling ship “CHIKYU” (<http://image.baidu.com/>)

azimuth propellers in the stern. Besides, it also has dynamic positioning capability with DPS-B, with 360° omnibearing observation.

**Chinese Geophysical Research Ship
“Haiyangdizhi Bahao”**

“Haiyangdizhi Bahao” is the first geophysical survey ship that is designed and constructed in China (shown in Fig. 4). It is capable of 3D or 4D high-precision short track seismic survey, equipped with six seismic cables, up to eight cables. It meets the demand of natural gas hydrate survey, regional geological survey, and resource exploration.

The ship has a length of 88 m, a width of 20.4 m, a depth of 8 m, a draft of 6.2 m, and a maximum speed of 15.4 kn. It can sail 16,000 nm under 12.1 kn continuously. It is a double-skin ship equipped with double catheter controllable pitch propellers. The electric propulsion system is made up of four main generators and one berth generator, with double-layer vibration isolation system. In addition, it is satisfied with the environmental protection requirements of CLEAN class notation by China Classification Society (CCS). It is also qualified by COMF (NOISE3) and COMF (VIB 3) comfort class notation.

Research Ship, Fig. 4 Chinese geophysical survey ship “Haiyangdizhi Bahao” (<http://www.gmgs.cgs.gov.cn/>)

**Research Ship,
Fig. 5** Australian
oceanographic research
ship “Investigator” ([https://
www.csiro.au/](https://www.csiro.au/))

Australian Oceanographic Research Ship “Investigator”

“Investigator” is an Australian oceanographic research ship which was constructed in Singapore and is owned and managed by the Commonwealth Scientific and Industrial Research Organisation (CSIRO) (shown in Fig. 5). It is operated by the Australian Marine National Facility to undertake oceanographic, geoscience, ecosystem, and fisheries research (Australian Broadcasting Corporation 2014).

“Investigator” has a length of 93.9 m, a width of 18.5 m, a depth of 9.45 m, a draft of 6.2 m, and a maximum speed of 12 kn (Sabto BGM 2012). It is able to accommodate up to 40 scientists and go to sea for up to 60 days and 10,000 nm at a time. Special features of the ship are a “gondola,” similar to a winged keel, mounted 1.2 m below the hull, and two drop keels, which can be lowered to a maximum of 4 m below the hull, to carry scientific instruments below the layer of microbubbles created by the movement of the ship’s hull

Research Ship, Fig. 6 Germany fuel research ship “Atair II” (<http://image.baidu.com/>)

through the water (Brian et al. 2012). Such instrumentation includes acoustic mappers, a pelagic sediment profiler to produce maps of the sea floor, and two ADCP. The hull and the machinery of the ship have been designed to operate as quietly as possible to enhance its scientific capabilities.

Germany Fuel Research Ship “Atair II”

“Atair II” is the first research ship in the world with LNG as fuel, built by Germany Maritime and Hydrological Administration, expected delivery in 2020 (shown in Fig. 6) (Sun and Liu 2018). It is mainly applied in hydrological survey and wreck searching, as well as marine environment observation in the North Sea and the Baltic Sea. At the same time, it is the technical test platform for navigation and radar system.

“Atair II” has a length of 74 m, a width of 17 m, a draft of 5 m, and a capacity of 18 crew members and 15 scientists. It is satisfied with DNV GL classification and SILENT-R class notation. It also has one 6-cylinder Wartsila 20 diesel engine, two 1110 kW of Wartsila 20DF diesel engines, and two sets of exhaust gas cleaning system. The Wartsila LNGPac fuel system has the gas storage capacity of 130 m³, supporting the gas consumption of 10 days approximately. Besides, it also has dynamic positioning capability (Eworldship 2019).

Resistance

► AUV/ROV/HOV Resistance

Resistance of Polar Vessel

Chunyu Guo, Chunhui Wang and Chao Wang
Harbin Engineering University, Harbin, China

Introduction

When a ship is transiting in ice-covered water, there will be ice resistance on the hull due to the ship-ice interaction. The ice resistance components depend on the ice conditions, such as level ice or brash ice, and thus the magnitude of the components will vary. The total ice resistance is

given as summation of open water resistance and ice resistance, where ice resistance consists of breaking, submersion, and friction resistance. The breaking resistance depends on bow shape, ice thickness, and ice strength, while the submersion resistance will vary with the bow shape and ice thickness, and the friction resistance will depend on the hull form, speed, and thickness of ice and snow. The ice resistance can be found from full-scale measurements during ice trials, by model tests, or by application of semiempirical and numerical ice prediction resistance methods, which are applied in an early design phase to indicate the ice resistance for different ice conditions.

Definition

When sailing in ice-covered water, there will be a force subjected to ice (level ice and crushed ice) and fluid (water and air) acting on the ship which is opposite to the movement of the ship. We call the force as polar ice resistance.

According to Riska (2011a), the ice resistance can be divided into three main force components: breaking forces, submergence forces, and sliding forces. The breaking forces are related to the moment where the ice is breaking, which includes crushing, bending, and turning of ice, and the submergence forces are related to the submerging of ice floes. The sliding forces will include the frictional forces between ship hull and ice, and due to the frictional forces, the ice resistance will be speed dependent (Riska 2011b).

R

Empirical Formula to Calculate Ice Resistance

Spencer Method

According to Spencer (Spencer 1992), the ice resistance can be divided into four main force components: forces from breaking the ice, forces from submerging the broken ice, forces from friction along the ship hull, and hydrodynamic forces.

$$R_T = R_{OW} + R_B + R_C + R_{BR} \quad (1)$$

where R_T is the total resistance, R_{OW} is open water resistance, R_B is submersion resistance, R_C is ice clearing resistance, and R_{BR} is breaking resistance. That is, the total resistance is composed of open water resistance, submersion resistance, ice clearing resistance, and breaking resistance.

The open water resistance mainly refers to the water resistance. When a ship passes through the open water (without ice), the open water resistance can be measured directly by the general tests in the ship model towing tank.

It is difficult to measure the individual ice resistance components by the real ship tests. However, the individual resistance components can be separated by changing the test conditions in the ship model tests conducted on ice tank. At a certain speed, the pre-cutting ice resistance of the model R_{PS} is measured under the pre-cutting ice condition, and the breaking resistance R_{BR} can be separated by subtracting the resistance under the pre-cutting ice condition from the total resistance. Among them, the pre-cutting ice resistance is:

$$R_{PS} = R_{OW} + R_B + R_C \quad (2)$$

The submersion resistance R_B is caused by the fact that the broken ice blocks squeezing of the bottom of the ship due to buoyancy, which accounts for 10–15% of the total resistance. If resistance R_{OW} in open water is known, ($R_B + R_C$) can be separated. It is assumed that the submersion resistance R_B is independent of velocity and the clearing ice resistance R_C is related to velocity. Therefore, the model resistance is measured at a very low speed under the condition of the pre-cutting ice floe. At this time, it can be considered that the ice clearing resistance is equal to zero because the ice clearing resistance is related to the velocity. Similarly, open water resistance is also equal to zero. In this way, submersion resistance can be separated in the very low-speed pre-cutting ice condition:

$$R_B = R_{PS(V=0)} = C_B \Delta \rho g h_i B T \quad (3)$$

In the formula, C_B is the submersion resistance coefficient, $\Delta \rho$ is the difference between the water density and the ice density, g is the acceleration of

gravity, h_i is the ice thickness, B is the width of the ship, and T is the draft of the ship.

As the broken ice slides along the hull's surface, it creates ice clearing resistance. The ice clearing resistance is obtained by subtracting the submersion resistance and open water resistance from the pre-cutting ice resistance. Ice clearing resistance accounts for 10–15% of the total resistance. Therefore, the ice clearing resistance can be expressed as:

$$R_C = R_{PS} - R_{OW} - R_B \quad (4)$$

If the open water resistance R_{OW} is known, it is possible to separate submersion resistance and ice clearing resistance R_C according to formulas (2, 3, and 4).

Breaking resistance accounts for the largest part of the total resistance, which can be expressed as:

$$R_{BR} = R_T - R_{PS} \quad (5)$$

Colbourne Method

Colbourne from the Institute of Oceanographic Technology of Canada, aiming at the ship model resistance test under the crushed ice condition and taking into account the different concentrations of crushed ice conditions, developed an analytical method to analyze ship model resistance tests under crushed ice conditions.

Unlike the Spencer method, Spencer assumes that the resistance of ice floe is speed independent, and the resistance of clearing ice is related to the speed. Colbourne regards the submersion resistance and the clearing ice resistance as a whole, that is, the total resistance of the ships in ice area under the condition of broken ice is divided into open water resistance and breaking resistance, and the relationship between breaking resistance is square to the velocity; Spencer did not consider the impact of crushed ice concentrations on breaking resistance, but Colbourne thought that breaking resistance and crushed ice concentration have a powerful relation where the value of resistance is different for different ship types.

In the case of broken ice, assuming that the size of the broken ice is small relative to the size of the ship and when the ship passes through broken ice

area, the occurrence of broken ice breakage is so small that the resistance caused by this breakage can be ignored. Then, the total resistance under broken ice conditions can be divided into two components: one is open water resistance, and the other is called crushed ice resistance due to various movements of broken ice around the hull (including sinking, turning, sliding, etc.). Among them, the open water resistance can be measured by the resistance towing test of the ship model towing tank. And the breaking resistance caused by broken ice movement is obtained by subtracting open water resistance from the total resistance measured by ship model resistance test under the broken ice condition. The total resistance under broken ice conditions can be expressed as:

$$R_T = R_{OW} + R_p \quad (6)$$

where R_{OW} is the open water resistance and R_p is the breaking resistance.

Lindqvist Method

In 1989, Gustav Lindqvist (Lindqvist 1989) proposed a method for calculating ice resistance. He divided the total resistance into three parts: ice-breaking resistance, underwater resistance, and velocity-dependent resistance (in which the ice-breaking resistance is divided into two parts: extrusion force of stern and bending destructive force).

Breaking Resistance

It is difficult to measure the stern squeezing pressure. It can be approximated by the probability method. The force of the vertical component acting on the ice F_V is estimated as

$$F_V = 0.5\sigma_f h_i^2 \quad (7)$$

where the σ_f is the bending strength of ice and h_i is the thickness of ice.

By analyzing the squeezing process and considering the geometry, the squeezing resistance R_C can be obtained:

$$R_C = F_V \cdot \tan \psi + \mu \cdot \frac{\cos \phi}{\cos \psi} / 1 - \mu \cdot \frac{\sin \phi}{\cos \psi} \quad (8)$$

where $\psi = \arctan \tan \phi / \sin \alpha$, ϕ is stem angle, α is angle of waterline entrance, and μ is friction factor.

Bending destructive force R_B can be expressed as

$$R_B = \frac{27}{64} \cdot \sigma_f \cdot B \cdot h_{ice} / \sqrt{\frac{E}{12(1-\nu^2)g\rho_w}} \cdot \tan \psi + \mu \cdot \cos \phi / \cos \psi \sin \alpha \cdot (1 + 1/\cos \psi) \quad (9)$$

where h_{ice} is ice thickness, E is Young modulus, ν is Poisson ratio, σ_f is ice bending strength, B is the breadth of the ship, g is the acceleration of gravity, and ρ_w is the density of seawater.

Underwater Resistance

Underwater resistance R_S consists of two parts: potential energy loss and friction resistance; the resistance value can be calculated by the formula:

$$R_S = (\rho_w - \rho_i) \cdot g \cdot h_{tot} \cdot B \cdot K \quad (10)$$

$K =$

$$\left\{ T \cdot B + T/B + 2T + \mu \cdot \left[\frac{(0.7L - T/\tan \phi - B/4 \tan \alpha) +}{T \cos \phi \cos \psi \sqrt{1/\sin^2 \phi + 1/\tan^2 \alpha}} \right] \right\} \quad (11)$$

where ρ_i is ice density, ρ_w is water density, T is extreme draft, L is the length of the ship, and h_{tot} is the total thickness of ice and snow.

Velocity-Related Resistance

Resistance associated with speed is more uncertain than other parts. According to the research, the resistance increases linearly with the increase in velocity.

Based on the above four parts, using the empirical constants to obtain the total resistance sailing in ice can be expressed as

$$R_i = (R_C + R_B) \cdot \left(1 + 1.4v/\sqrt{gh_i} \right) + R_S \cdot \left(1 + 9.4v/\sqrt{gL} \right) \quad (12)$$

Keinonen Method

By analyzing the resistance model data of several kinds of parent ships, the ice resistance of ice-

breaker at a speed of 1 m/s is obtained by this method (Keinonen and Browne 1991). The main parameters of the method are ship size, inclination angle, hull condition, the thickness of ice and snow, bending strength, salinity, and temperature of sea water. The ice resistance is expressed as:

$$R_{ice} = 0.015 \cdot (F_{si} \times F_{sh} \times F_i) \quad (13)$$

where F_{si} is size factor; F_{sh} is form factor; and F_i is ice factor.

After that, Keinonen analyzed the situation of velocity exceeding 1 m/s and put forward the expression of total resistance sailing in the ice area as follows:

$$R(v)_t = R(v)_{ow} + R(1m/s)_i + R(> 1m/s)_i \quad (14)$$

where $R(v)_t$ is total resistance at velocity v ; $R(v)_{ow}$ is open water resistance at velocity v ; $R(1m/s)_i$ is ice resistance at 1 m/s; and $R(> 1m/s)_i$ is resistance increases at speeds above 1 m/s.

Riska Method

Riska's formula (Riska et al. 1997) for calculating resistance is also based on a series of empirical coefficients, in which the empirical coefficients are obtained from multiple sets of real ship tests of different types of ships in the Baltic Sea.

The main expression formula of Riska resistance is $R_T = R_{openwater} + R_{ice}$. The resistance sailing in the ice is divided into two parts: open water resistance $R_{openwater}$ and the resistance R_{ice} caused by ice. At present, the prediction method of open water resistance of ships is relatively mature. However, there are two parts for the resistance in ice R_i : inertial resistance related to velocity and direct resistance independent of velocity. The expression formula is as follows:

$$R_i = C_1 + C_2 V \quad (15)$$

where

$$C_1 = f_1^{1/2T/B+1} B L_{par} h_i + (1 + 0.0021\phi) \cdot (f_2 B h_i^2 + f_4 B L_{bow} h_i) \quad (16)$$

$$C_2 = (1 + 0.063\phi) \cdot (g_1 \cdot h_i^{1.5} + g_3 \cdot B \cdot h_i) + g_3 \cdot h_i \cdot (1 + 1.2T/B) \cdot B^2/\sqrt{L} \quad (17)$$

L , B , and T indicate the length, width, and draft of the boat, respectively; ϕ is bow inclination, h_i is ice thickness, and L_{par} and L_{bow} are the length of the parallel middle body and the length of the bow, respectively. The empirical coefficient f , g in the formula is given in Table 1 (ITTC 2017).

Enkvist Method

$$R_{TOT} = C_1 B h \sigma + C_2 B h T \rho_{\Delta} g + C_3 B h \rho_i v^2 \quad (18)$$

where R_{TOT} is ice resistance; B , T represents the width and draught of the ship, respectively; h is ice thickness; σ is ice bending strength; ρ_i is ice density; ρ_{Δ} is density difference between water and ice; g is the acceleration of gravity; v is the speed of the ship; and $C_1 C_2 C_3$ is the dimensionless factor (ENKVIST 1972).

In the test, the velocity-related terms can be isolated by comparing at low speed ($v \approx 0$) and normal speed; and the sinking items can be isolated by performing the pre-cutting ice ($\sigma = 0$) test. This experimental design method can determine the relative importance of the three resistance components in the equation.

Finnish-Swedish Ice Class Rules Method

The Finnish-Swedish Ice Class Rules (2002) provide a formula for the resistance of a ship sailing in the broken ice:

Resistance of Polar Vessel, Table 1 coefficient of Riska's formula

Variable	Value
f_1 (kN·m ⁻³)	0.23
f_2 (kN·m ⁻³)	4.58
f_3 (kN·m ⁻³)	1.47
f_4 (kN·m ⁻³)	0.29
g_1 (kN·s·m ^{-2.5})	18.9
g_2 (kN·s·m ⁻³)	0.67
g_3 (kN·s ¹ ·m ^{-3.5})	1.55

$$\begin{aligned}
R_{ch} = & \frac{1}{2}\mu_B\rho_{\Delta}gH_F^2K_p\left[\frac{1}{2} + \frac{H_M}{2H_F}\right]^2 \\
& \cdot [B + 2H_F(\cos\delta - \frac{1}{\tan\psi})] \\
& \cdot (\mu_h \cos\phi + \sin\psi \sin\alpha) \\
& + \mu_B\rho_{\Delta}gK_0\mu_hL_{par}H_F^2 \\
& + \rho_{\Delta}g\left(\frac{LT}{B^2}\right)^3H_MA_{WF}F_n^2
\end{aligned} \quad (19)$$

where $\mu_B = 1 - p$; p is porosity ($\mu_B = 0.8 \sim 0.9$); ρ_{Δ} is difference between ice and water density; g is acceleration of gravity; K_p is passivation stress (soil mechanics); δ is the inclination of the side-wall of broken ice; μ_h is coefficient of friction between ice and hull; L , B , and T are, respectively, represented the length, width, and draft of the ship; ϕ is the included angle between the waterline and the mid-longitudinal section line; ψ is angle of flare; α is waterline incident angle; K_0 is static lateral pressure coefficient; L_{par} is the length of a parallel middle body at the waterline; A_{WF} is waterplane area at the bow of the hull; F_n is Froude number; H_M is the thickness of broken ice in the middle of waterway; and H_F represents the thickness of the broken ice moving from the bow to both sides of the parallel middle body. It is a function of the width of the ship, the thickness of the channel, and the two slanting angles γ and δ depending on the internal properties of the broken ice (generally $\gamma = 2^\circ$, $\delta = 22.6^\circ$), as follows:

$$\begin{aligned}
H_F = & H_M + B/2 \tan\gamma + (\tan\gamma + \tan\delta) \\
& \times \sqrt{B\left[H_M + \frac{B}{4}\tan\gamma\right] / \tan\gamma + \tan\delta}
\end{aligned} \quad (20)$$

when $B > 10$ m and $H_M > 0.4$ m, the formula can be approximately simplified to

$$H_F = 0.26 + (BH_M)^{0.5} \quad (21)$$

Angle of flare ψ can be eliminated from the formula on the basis of the following triangulation:

$$\begin{aligned}
\sin\psi &= \tan\phi / \sqrt{\sin^2\alpha + \tan^2\phi} \\
\psi &= \arctan(\tan\phi / \sin\alpha)
\end{aligned} \quad (22)$$

It can be seen that the ship resistance in floating ice zone can be preliminarily estimated by the

Finnish-Swedish standard if the ship lines, principal dimensions, and the correlation property coefficient of floating ice are given.

Numerical Modeling of Ice Resistance

Discrete (Distinct) Element Method (DEM)

Discrete element method (distinct element method, DEM) already has a long history of deployment in the field of ice mechanics. Open source implementations are also available. For example, LIGGGHTS implements DEM (Kloss et al. 2012; Morgan et al. 2015; Morgan 2016; Yulmetov et al. 2017) and employed this software to simulate ice structure interaction.

Smoothed Particle Hydrodynamics (SPH) and Moving Particle Semi-Implicit Method (MPS)

Smoothed particle hydrodynamics (SPH) is one of the Lagrangian methods to handle continuum mechanics. It was originally developed for fluid simulations but is now extended to handle solid mechanics. Some commercial software such as LS-DYNA implements SPH to handle fluid and/or solid simulations.

Moving particle semi-implicit (MPS) method was separately developed and investigated with SPH as an implementation of incompressible fluid simulation but can be considered as an implementation of SPH with different spatial discretization schemes. Recently, it is also extended to handle solid mechanics. Ren et al. (2017) deployed this method to simulate the interaction of an ice beam and a large water droplet.

Fluid-Structure Coupling

Fluid-structure interaction (FSI) is one of the most important but difficult fields of investigation with numerical simulations. However, a few commercial packages implement FSI recently so that it becomes easier.

Song, Kim, and Amdahl (Song et al. 2015) employed LS-DYNA to investigate collision of the steel structure with an ice floe. Shigihara, Ishibashi, and Konno (2015) employed STAR-CCM+ to investigate collision of a ship with a single ice floe. Vroegrijk (2015) also employed

STAR-CCM+ to investigate ship navigation in brash ice channel.

Model Test of Ice Resistance

The model test of ice resistance is introduced in the Specialist Committee on Ice, Technical Committees and Group of the 28th ITTC.

Methods to Determine Ice Resistance Using Self-Propelled Model Test

An increasing share of self-propulsion model tests is one of the modern trends in test practices of ice basins. Most leading ice basins took to using self-propelled models rather than non-propelled models in ice resistance towing tests.

Method of Krylov State Research Center

(1) First Method

Traditionally, in the KSRC ice basin practices, the self-propelled models have been used to find ice resistance of model in astern mode. In this case, the captive test method is employed when a model is rigidly fixed to the towing carriage via dynamometer and outfitted with running propellers, as shown in Fig. 1. Propeller thrust is measured with special-purpose dynamometers.

For a propelled ship model running astern, the ice resistance R_I is found from the following force equation:

$$R_I = -(F_{means} + (1 - t) \cdot \sum_i P_i) \quad (23)$$

where F_{means} , force measured by dynamometer; t , thrust deduction factor; and $\sum_i P_i$, total thrust of propellers.

(2) Second Method

A model with running propellers is towed at a specified speed by towing carriage. The force of model-carriage interaction F_I is measured. The speed of propeller rotation is chosen to match the propulsive thrust with the model speed. In this case, a close to full-scale flow pattern around the hull is obtained. Experiments in a continuous ice sheet, when completed, leave a channel packed up with brash ice. This channel after being cleared of brash ice is used to repeat the self-propelled model tests, now in open water. These experiments are conducted at the same speed of propeller rotation and model speed to measure the force of model-carriage interaction F_W .

The pure ice resistance force R_I is calculated based on the test data obtained in ice and open water conditions using Eq. (24):

$$R_I = F_I + F_W \quad (24)$$

It should be noted that the forces F_I and F_W retain their actual signs when being summed up.

Rigid connection between the self-propelled model and towing carriage makes it possible to accurately set the model speed in ice. The force between towing carriage and model measured by dynamometer indicates whether the propeller

Resistance of Polar Vessel, Fig. 1 Astern test setup: 1, dynamometer; 2, ship model hull; 3, propulsion pod model (Specialist Committee on Ice, Technical Committees and Group of the 28th ITTC, 2017)

thrust is higher than the ice-plus-water resistance or not sufficient to overcome this total resistance. This force is defined by Eq. (25):

$$F_I = R_I + R_W - T_E \quad (25)$$

where R_W – model resistance due to water and T_E – effective thrust of model's propulsion system. Model tests in a channel cleaned of brash ice make it possible to determine the hydrodynamic resistance force F_W more accurately than it is done using the Finnish method because in these tests, the hydrodynamic resistance has practically no wave-making component. In ice basin, the hydrodynamic resistance should be determined following all requirements which are applied to the same kind of experiments when conducted in towing tanks. In these tests the force between model and towing carriage is determined, which is defined according to Eq. (26):

$$F_W = T_E - R_W \quad (26)$$

From Eq. (25) follows the ice resistance in Eq. (27)

$$R_I = F_I + T_E - R_W \quad (27)$$

Then the final formula for the ice resistance is Eq. (24).

Method of Aker Arctic

The ice basin of Aker Arctic is using a different technique involving a series of preliminary open water tests usually carried out in the ice basin itself. Under this method, ice resistance is determined using self-propulsion tests at the ship propulsion point.

Model ice resistance is determined in a number of steps. Self-propelled model is tested under bollard pull condition in open water. In this case, the propeller thrust is measured at different propeller speeds. These data are then used to find the speed which provides the specified thrust of propulsion system in bollard pull condition. Towing tests of the model with running propellers are performed in open (ice-free) water with the model fixed to the towing carriage via dynamometer. Propellers are

run at speeds corresponding to 80, 100, and 120% power consumption. In these tests the brake force (which is applied from the towing carriage side to model) is measured versus model speed (at constant number of revolutions that could be different for side propellers and middle propeller). The open water tests give brake force versus model speed.

Method of HSVA

HSVA ice basin is using both self-propelled and non-propelled models in ice resistance tests. Ice resistance tests with self-propelled models are performed in a captive setup. The model is towed at a given speed, while propeller revolution numbers are varied. Propeller revolutions range from practically zero to a certain value specified to assure that the force recorded by dynamometer changes its direction (model now pulling the towing carriage). As shown in Fig. 2, a mandatory test condition is practically zero number of propeller revolutions. Based on the results of this test, the ice resistance of model is found.

Model Ice in Ice Resistance Experiment

Type ice can be divided into two categories: frozen model ice and nonfrozen model ice. The frozen model ice is mainly used in the ice basin laboratory at home and abroad, and the non-freezing model ice is mostly used in the conventional towing tank laboratory without an ice basin.

The frozen model ice is divided into brine ice, urea ice, and EG/AD/S ice. Brine ice, also known as the first-generation model ice, is made from a certain concentration of sodium chloride solution (Schwarz 1977). Urea ice, also known as the second-generation model ice, is made up of a 1.3% concentration of urea solution (Timco 1979, 1980; Hirayama 1983).

The EG/AD/S ice, also known as the third-generation model ice, is made from aqueous solutions of three different additives including the mixture of ethylene glycol (EG), aliphatic detergent (AD), and sugar (S) (Timco 1986).

With the development of experimental technology and the requirements of ice zone tests, various kinds of nonfreezing synthetic model ice have come out one after another. The advantages

Resistance of Polar Vessel, Fig. 2 Determination of ice resistance by HSVA method (HSVA Report 2012)

of nonfreezing model ice are that it does not require low-temperature manufacturing and it's easier to control. At present, the main model ice used in ice ship resistance test are fragments of semi-refined paraffin wax and polypropylene material, as shown in Fig. 3.

Two Methods to Conduct the Towing Tests

The methods to conduct the towing tests can be found in the website of HSVA ice tank (<https://www.hsva.de/our-services/model-testing/tests-in-the-ice-tank.html>).

Towed Propulsion

During the towed propulsion test, the model is connected to the service carriage, which is pushed by the main carriage, via a rigid rod that itself is attached to a load cell at the bows of the model, as shown in Fig. 4. After being accelerated the model is towed at a constant speed. The propeller rpm is changed in four steps from near idling condition through a value close to the self-propulsion point up to a value well above the self-propulsion

condition. Both the thrust of propellers and the coupling force are measured, and therefore the actual propulsion point for the given speed can be determined throughout interpolation from the linear correlation between thrust and pull force. The resistance can be read from the intersection point of the same curve with the axis of ordinates.

Fixed Mode Testing

Regardless of the type, each model can be tested in fixed mode. This means the models' motion is blocked in a number of degrees of freedom, as shown in Fig. 5. This can be partially inferred that only certain directions of motion are blocked or completely – in this case all six degrees of freedom are blocked. Ice-induced vibrations can be investigated in a fixed mode where the model is rigidly connected to the basin floor, and only motions in one or two directions are allowed. Ice loads on a vessel may be determined in a fixed setup where the vessel is rigidly connected to the main carriage and pushed through the ice. A special rotation platform allows testing the

subject, vessel, or structure, under certain oblique angles. In all cases, forces in three axes and moments around these axes are determined by means of a six-component scale. In addition to the forces accelerations, velocities and movements of the structure/vessel will be measured.

Definition

Resource assessment is an evaluation of the long-term available offshore renewable energy resources (in terms of energy or power), including wind, wave, and marine current energy resources. This can be done from a global and regional perspective for site screening/selection or for a specific location for the development of commercial farms. Offshore renewable energy resource can also be distinguished as potentially available resource (assuming that all the energy can be converted into electricity) or technically available resource (which can be practically converted by a given device or technology and therefore is device- and site-specific).

Wind Energy Resource

Wind energy refers to the kinetic energy of air in motion, and the total wind energy during a period of t through an area of A normal to the mean wind direction is $E = \frac{1}{2} A \rho U^3$, where ρ is the density of the air and U is the mean wind speed. Then the power is the energy per unit time $P = \frac{1}{2} A \rho U^3$. Often, we use the wind power density $\frac{P}{A} = \frac{1}{2} \rho U^3$ for resource assessment and spatial distribution of wind power. In addition to the parameter of mean wind speed, turbulent intensity factor is often estimated based on measurements or simulations, and it is a very important parameter that is related to dynamic loads and responses of offshore wind

turbines, although it is not so important for power estimation.

Figure 1 shows the global spatial distribution of average offshore wind power density with respect to the winter and the summer seasons of the Northern Hemisphere (NASA/JPL 2008). It clearly shows the non-uniform distribution of the wind power density around the globe, with larger wind power in northern or southern areas than that near the equator. The equator area has less variation in wind power density (and therefore wind speed) among different seasons, while wind speed in winter is much larger than that in summer for the northern or southern area. Because of the considerations on economics and survivability of offshore wind turbines, it is not expected to see in the near future wind turbines in the middle of oceans, far from the shore. Offshore wind is now being developed from near shore gradually towards deeper waters.

The available power in wind is proportional to the cube of wind speed. Therefore, an accurate estimation of the mean wind speed is important for resource assessment. However, the mean wind speed also varies vertically, increasing when the height from the sea surface increases, which is referred to as wind shear. Figure 2 shows the annual mean wind speed distribution offshore Europe for five standard heights. Most of the offshore wind turbines today have a nacelle height between 70 m and 100 m. The mean wind speed at the height of 100 m is larger than 10 m/s for the northern North Sea area, while it is about 8.5–10 m/s for the North Sea and 6–8.5 m/s for the Mediterranean Sea.

If we consider a mean wind speed of 12 m/s as the rated wind speed of an offshore wind turbine and a maximum efficient of 50%, a rotor area of 11,600 m² and therefore a blade length of 60 m are needed to produce 5 MW of electric power.

On the other hand, the mean wind speed varies also in time. From a long-term perspective (i.e., 25 years of lifetime), a probabilistic distribution (for example, Weibull distribution) of mean wind speed for a given site is typically established using either measurement data or hindcast data (see Li et al. 2015). Such wind speed distribution can be used in combination with the wind turbine power

Resource Assessment, Fig. 1 Global distribution of offshore wind power density in winter and summer (NASA/JPL 2008)

curve to estimate the annual power output from a turbine or from a farm.

As of today, there are many wind resource maps that are already developed at the global level by government or research agencies, as shown in Fig. 1. More detailed regional and local wind resource assessment, using either numerical models or in situ measurements (such as WASP – Wind Atlas Analysis and Application Program (Mortensen et al. 2005)), is needed for developing commercial offshore wind farms. Satellite-borne remote sensing observations, purpose-built meteorological masts, and ground-based remote sensing techniques (such as SODARs – Sonic Detection and Ranging; LIDARs – Light Detection and Ranging) are developed for specific wind speed measurement and resource assessment (Sempreviva et al. 2008).

Wave Energy Resource

Energy in propagating gravity ocean waves contains both kinetic and potential energy, which alternates when the waves propagate. It is the wave kinetic energy that can be absorbed and converted into electricity using a wave energy converter device.

For a regular wave with a height of H , the average energy E stored on a horizontal water surface with a unit area is $E = \frac{1}{8} \rho g H^2$, where ρ is the density of the sea water and g is the gravitational acceleration (Falnes 2002). Wave power P , which is the wave energy flux through a vertical plane of unit width perpendicular to the wave propagation direction, is $P = c_g E = \frac{1}{32\pi} \rho g^2 T H^2$, where c_g is the group velocity and T is the wave period. For example, when $H=2\text{m}$, $T=10\text{s}$, we can get $P=40\text{kW/m}$. For an irregular

Resource Assessment, Fig. 2 Distribution of annual mean wind speed and wind power density offshore Europe (Troen and Lundtang Petersen 1989)

wave with significant wave height H_s and wave energy period T_e , the wave energy flux becomes $P = \frac{1}{64\pi} \rho g^2 T_e H_s^2$. For example, when $H_s = 2\text{m}$, $T_e = 10\text{s}$, we can get $P = 20\text{kW/m}$. It should be noted that the wave power is proportional to wave period and wave height squared. Although they are not sensitive as wind speed for wind power,

there exists a big difference in wave power for small and large waves. Figure 3 illustrates a map of global annual mean wave power (Mørk et al. 2008). This map indicates that the highest levels of average wave power are found in the areas between 40° and 60° in both hemispheres, which are consistent with the observations for global

Resource Assessment, Fig. 3 Global distribution of annual mean wave power (Mørk et al. 2008)

mean wind speed distribution as shown in Fig. 1. Like offshore wind resource, it is not possible to utilize all the wave energy in oceans based on the current technology and only the ocean areas close to the shore are relevant. High annual average wave power, typically 40–100 kW/m, is found along the coastlines of northern Europe, North America, South Africa, Australia/New Zealand, and Chile/Argentina.

Considering a site with annual average wave power of 40 kW/m and a device of 25% efficiency for electricity generation, the device needs to be at least 500 m long in order to produce 5 MW of electric power. This indicates that a large device is needed, which is particularly challenging when developing commercial wave energy converters since the cost will be high.

Wave power at a given offshore site also shows a variation in time. Since wave power is a function of both wave height and period, the long-term variation of wave power can be determined using the long-term joint distribution of significant wave height and spectral wave period (or wave energy period), as shown by Li et al. (2015). For a given wave energy converter device, the power absorption varies with respect to significant wave height and spectral wave period.

A combination of the wave power matrix of the device with the long-term distribution of significant wave height and spectral wave period can be used to derive the annual power output.

Global and regional distribution of wave power can be estimated based on wave buoy measurements, satellite remote data, or numerical models. The results in Fig. 3 were based on the data from the ECMWF (European Centre for Medium-Range Weather Forecasts) WAM numerical model, which is calibrated and corrected by Fugro OCEANOR against a global buoy and Topex satellite altimeter database (Mørk et al. 2008).

High-resolution numerical models are developed for resource assessment of a specific site, including the prediction of wave energy, heights, periods, and directions. Two types of approaches are used in these numerical models: (1) the deterministic approach, which describes the sea surface evolution accurately in both time and space; and (2) the spectral approach, which provides a statistical description of the wave conditions in space and time. The first approaches can capture all the relevant physics of wave/bottom/shoreline and nonlinear wave-wave interactions, but they are computationally expensive. The spectral

approaches provide an approximation of the physics of nonlinear wave-wave interaction, wind forcing, and wave breaking/bottom dissipation. But they are commonly used today and typically are open-source and user-friendly, such as MIKE21 (2008), SWAN (2009), TOMAWAC (2014). A comparison of the different numerical wave models was carried out and can be found in Venugopal et al. (2010).

Ocean and Tidal Current Energy Resource

Ocean current might be generated due to many mechanisms, including tidal effect, ocean circulation, and wind generation. Here, we focus on tidal energy. Like offshore wind energy, ocean current energy refers to the kinetic energy in ocean current, which can be characterized using the current speed or velocity. However, since the density of sea water is much larger than that of air, one doesn't need a very large rotor area of a tidal turbine to achieve the same power production as compared to a wind turbine, although current

speed is typically much lower than wind speed. For example, considering a tidal current velocity of 3 m/s and 50% of efficiency of the turbine, a rotor with a diameter of 30 m (instead of 120 m for wind turbines at the rated wind speed of 12 m/s) can produce 5 MW of electric power.

Tidal energy resource can be very well predicted and shows a 12-h variation. It is strongly dependent on the tidal range at different locations. Figure 4 shows a global distribution of tidal range, which represents the tidal current speed and energy (NASA 2006). It shows that a strong location-dependent and places with abundant tidal energy are limited. In Europe, UK and Ireland have large resource, while some areas in the west coasts of Australia, New Zealand, Canada, and the east coast of the USA and China also have large potential to develop tidal energy.

Most of the tidal energy resource assessment is performed based on current speed measurements using for example Acoustic Doppler Current Profilers (Thomson et al. 2012) or Marine Radar (Bell et al. 2012), in particular in local straits or channels, where current speed can reach the minimum value for efficient use of tidal turbines and for

Resource Assessment, Fig. 4 Global distribution of tidal range (NASA 2006)

commercial development (Bahaj 2013). Numerical models based on 2D or 3D formulations have also been developed and used for resource assessment (Venugopal and Nimalidinne 2014). An offshore site with significant tidal energy resource often has large turbulence and large waves, which might be challenging for structural design of tidal turbines.

Heilongjiang, China

Synonyms

Reliability-based design

Definition

In engineering applications, as decision support tools, risk and reliability analysis methods are increasingly recognized worldwide. Risk-based design is a process integrating the risk and reliability analysis methods into product design. Risk-Based Ship and Offshore Structures Design introduces risk analysis into the traditional design process, aiming to deal with safety problems reasonably and effectively (Apostolos 2009).

Scientific Fundamentals

Principle of Risk-Based Design

The International Maritime Organization (IMO) has discussed the target based criteria and given rise to the term “Safety Level” designating the through-life level of acceptable risk associated with a particular ship concept, which may lead to a new guiding principle to attaining safety cost-effectively. The concept of “risk” is often associated with unexpected events and with shipping operations being undoubtedly “risky,” which

must be remembered when designing ship and offshore structures.

Effective risk management at the design stage is extremely important. At this stage, commencing with concept development or selection, there is the greatest scope to adopt or devise arrangements which will reduce, or even eliminate, particular risks. Risk assessment should be undertaken as an integral part of the design process, so that risk management decisions can be taken in good time. Much of the potential benefit of risk assessment of the design will be lost if it takes place after the design has been firmed up. It should not simply be used to retrospectively justify design decisions already taken.

Safety features incorporated into the design will be more secure, long lasting, and effective than those that rely upon the use of safety equipment or the adoption of operating procedures intended to compensate for design deficiencies. Furthermore, as the design and construction work progress, it will become increasingly difficult and costly to incorporate safety related features.

Safety considerations in design can be considered in the following hierarchy:

- (a) Eliminate the hazard
- (b) Reduce the likelihood of a hazardous event, giving preference to inherent safety over operational safeguards (e.g., procedures)
- (c) Reduce the consequences of a hazardous event, for example, by reducing combustible fuel inventory; by adopting fail-safe or fault tolerant systems; by protecting structure and equipment from fire.
- (d) Protect people from the effects; collective protection in preference to individual protection
- (e) Provide means of escape and evacuation

The application of risk-based design is more focused on the concept of high level innovation (shown in Fig. 1), so it is necessary to use knowledge of ship information in all its forms: best practice, engineering evaluation, latest tools and data, and all content of quantitative risk analysis.

Risk-based design is a comprehensive approach. The key to understanding this method

is the integration of risk assessment in the design process and decision-making towards achieving the overall design goals, as illustrated by framework of Fig. 2.

Safety Assessment

The hazards caused by risks of ships and offshore structures mainly include the following three

aspects: casualty, environment disruption, and economic loss (Zhang et al. 2003), shown in Fig. 3.

- (a) The risks of personnel include: potential casualties, fatal accident rates, average individual risk rates, etc.
- (b) The degree of damage to the environment can be measured according to its recovery time. It

Risk-Based Design for Ship and Offshore Structures, Fig. 1 Risk-based design and innovation (Apostolos 2009)

Risk-Based Design for Ship and Offshore Structures, Fig. 2 Framework for risk-based design (Apostolos 2009)

Risk-Based Design for Ship and Offshore Structures,
Fig. 3 Content of safety assessment (Zhang et al. 2003)

can be generally divided into: 1–12 months, 1–3 years, 3–10 years, greater than 10 years, etc.

- (c) Economic loss usually refers to material damage and production delay.

Security Goals

Security goals, like other design objectives, are related to the mission and purpose of ships. Clear security goals are already part and parcel of the design input. Examples of design objectives driven by safety factors include (Christian et al. 2012):

Top-Level Goals:

- (a) No accident can cause loss of the whole ship, such as collision, grounding, fire, etc. (Franz 2010).
- (b) No loss of human life due to ship related accidents.
- (c) Low impact to the environment (no air emissions, low noise).
- (d) When the ship has an accident, the impact will be minimized.

Specific Technical Goals:

- (a) Vessels remain upright and afloat in all feasible operational loads and environmental conditions.
- (b) Vessels remain upright and afloat in case of water ingress and flooding.
- (c) The ship structure can withstand all predictable loads throughout the life cycle.
- (d) Sufficient residual structural strength in the case of breakage.
- (e) High passenger comfort (no seasickness, low vibration level, low noise level).

In general, the ship can meet all kinds of requirements for its use.

Key Applications

Risk Measurement

The risk for ship and offshore structures can be expressed by probability and resulting value. In actual calculation, the basic expression of the risk is:

$$R = \sum_i p_i \times c_i$$

where p_i represents the frequency of occurrence of a single event and c_i represents the consequences of the event.

Design Phase Using Risk Criteria

When adopting risk based ship design method, different risk assessment criteria can be adopted in different design stages.

The feasibility design phase of ship engineering: usually, decisions need to be made under the premise of less information, such as project progress, cost budget, etc. Qualitative or semi quantitative risk assessment methods are mainly adopted. The risk matrix of qualitative assessment is shown in Fig.4.

The detailed design phase of ship engineering: with the clarity of design objectives and various design parameters and drawing on existing databases, probability based quantitative risk assessment methods can be adopted. At this point, the ALARP principle can be used for quantitative risk assessment of casualty risk, environmental risk, and property risk, as shown in Fig.5.

A qualitative ranking of both frequency (from frequent through to incredible) and severity (from catastrophic to negligible) of each hazard is deduced by consensus.

These can be amalgamated in matrix form where the risk categories are:

A = Intolerable

B = Undesirable and only accepted when risk reduction is impracticable

			Potential Consequences				
			L6	L5	L4	L3	L2
			Minor injuries or discomfort. No medical treatment or measureable physical effects.	Injuries or illness requiring medical treatment. Temporary impairment.	Injuries or illness requiring hospital admssion.	Injury or illness resulting in permanent impairment.	Fatality
			Not Significant	Minor	Moderate	Major	Severe
Like lihood	Expected to occur regularly under normal circumstances	Almost Certain	Medium	High	Very High	Very High	Very High
	Expected to occur at some time	Likely	Medium	High	High	Very High	Very High
	May occur at some time	Possible	Low	Medium	High	High	Very High
	Not likely to occur in normal circumstances	Unlikely	Low	Low	Medium	Medium	High
	Could happen, but probably never will	Rare	Low	Low	Low	Low	Medium

Risk-Based Design for Ship and Offshore Structures, Fig. 4 Risk matrix (<https://cn.bing.com/>)

Risk-Based Design for Ship and Offshore Structures, Fig. 5 ALARP principle (<https://cn.bing.com/>)

C = Tolerable with the endorsement of the project safety review committee
D = Tolerable subject to normal project review

Risk acceptance criteria may be employed in supporting a design for ship and offshore structures when either classification or statutory approval is sought (Ship Right Design and Construction 2018).

Linking Risk-Based Design and Acceptance

Risk-based design for Ship and Offshore Structures is considered an enhanced variant of the traditional design process, taking safety as an additional design objective. Hence, an additional constraint is entered into the design optimization, as shown below (Jan 2007):

$$R_{design} \leq R_{acceptable}$$

With R_{design} the risk of the considered ship or offshore structures and $R_{acceptable}$ the acceptable risk.

Usually, risk is determined by the frequency and consequences of events. Different risk categories need to be distinguished, such as human life, environment, or property.

The design risk R_{design} is typically the sum of some risks associated with different types of accidents, such as collision, fire, or grounding. With the help of risk model, such as fault tree and Bayesian networks, each partial risk can be calculated.

The acceptable risk $R_{acceptable}$ of human life and environmental protection is specified by the approval authority (flag state administration and/or classification society). There are two options for determining acceptable risk: relative or absolute. In the first case, a reference design is selected which complies with current rules. In the second case, IMO risk acceptance criteria are used or referenced.

Techniques of Quantitative Risk Assessment

Quantitative risk assessment is the term most often used to describe the use of statistical or more properly quantitative methods in risk-based design. Quantitative techniques widely used under the risk-based design for Ship and Offshore Structures include:

- (a) Failure Modes, Effects and Criticality Analysis (FMECA)
- (b) Fault Tree Analysis (FTA)
- (c) Event Tree Analysis (ETA)
- (d) Statistical analysis of historical accident data
- (e) Reliability analysis of component failure data
- (f) Data elucidation from structured expert judgment
- (g) Human error analysis
- (h) Cost Benefit Analysis (CBA)

Decision Making

So far the assessment and ranking of risk has been considered. The final stage involves hard decisions where the proposed safety improvements may be difficult and the cost to implement considerable.

The principle of As Low As Reasonably Practicable ALARP (see “[Design Phase Using Risk Criteria](#)”) shows that tolerable risk is not a simple

pass/fail test. The majority of risks are in the ALARP region where work should be done to reduce the risk further.

The owners of each risk must be satisfied that safety arguments, criteria, and decisions are sound and documented so as to provide an audit trail. Peer review and the use of independent safety assessment/audit are also valuable in giving strength to decisions and actions, particularly if later challenged.

By taking safety as the target in the design process, the new concept of “safety design” and the development of risk-based design method can deal with ship safety in a systematic and comprehensive way. Risk-based design opens the door to innovation and provides competitive advantages for the maritime industry by facilitating cost-effective safety. It is impossible to optimize the design solutions without risk-based design.

This method reflects the trend of target based standards and highlights the advantages of risk-based design methods. It is particularly useful in the face of innovative ship and offshore structures design concepts and alternative design and arrangements. In this case, quantitative risk analysis is the only reliable way to ensure a suitable safety level and set a safety target.

ROV Dynamic Positioning

Biao Wang
Shanghai Engineering Research Center of Hadal Science and Technology, Shanghai Ocean University, Shanghai, China

Synonyms

Dynamic positioning (DP); Dynamic positioning control; Dynamic positioning control system; Dynamic positioning of remotely operated vehicles; Dynamic positioning of underwater robotic vehicles; Dynamic positioning system

Definition

The remotely operated vehicles (ROVs) dynamic positioning (DP) is a method to automatically

maintain an ROV on its position and/or heading (fixed location or predefined track) by use of its thrusters. ROVs equipped with DP system allow operations close to the seafloor, including station keeping, trajectory tracking, path following, and low-speed maneuvering. Then the pilot can focus on monitoring and planning of operations that demand human intervention or decision making.

Scientific Fundamentals

Historical Development

DP system was born with the increasing demands of the rapidly expanding oil and gas exploration industry in the 1960s and early 1970s. In the 1960s, the first DP system was introduced for horizontal modes of motion (surge, sway, and yaw) using single-input single-output PID control algorithms in combination with low-pass and/or notch filter (Sørensen 2011). The first ship to fulfill the accepted definition of dynamic positioning was the “Eureka” (1961), as shown in Fig. 1, of about 450 t displacement and 130 ft. length. This ship was fitted with an analog control system, interfaced with a taut wire reference, equipped with steerable thrusters fore and aft in addition to her main propulsion (Fay 1989).

ROV Dynamic Positioning, Fig. 1 The world's first DP vessel Eureka (Steinbeck 2017)

DP system development came in the mid-1970 with the application of Kalman filters and linear quadratic (LQ) optimal controllers. After 1995, nonlinear PID control, passive observer design and observer back-stepping designs have been applied to DP (Fossen 2002). In 1980, the number of dynamic positioning capable ships was about 65, in 1985, the number had increased to about 150. Currently (2013), it stands at over 1,800 and is still expanding (► “Dynamic Positioning in Ice” from Wikipedia).

DP systems have become more sophisticated and complicated, as well as more reliable. The costs are falling due to newer and cheaper technologies, and the advantages are becoming more compelling as offshore work enters ever deeper water and the environment is given more respect. Computer technology has developed rapidly and some vessels have been upgraded twice with new DP control systems. Position reference systems and other peripherals are also improving and redundancy is provided on all vessels designed to conduct higher-risk operations.

DP of underwater vehicles like ROVs and autonomous underwater vehicles (AUVs) has lately received increasing interest from offshore contractors, vendors, and the research community.

DP Classification

Based on IMO – International Maritime Organization publication 645 (IMO 1994), the classification societies have issued rules for dynamically positioned ships described as Class 1, Class 2, and Class 3.

Equipment Class 1 has no redundancy. Loss of position may occur in the event of a single fault.

Equipment Class 2 has redundancy so that no single fault in an active system will cause the system to fail. Loss of position should not occur from a single fault of an active component or system such as generators, thruster, switchboards, remote controlled valves, etc. But the loss of position may occur after the failure of a static component such as cables, pipes, manual valves, etc.

Equipment Class 3 which also has to withstand fire or flood in any one compartment without the system failing. Loss of position should not occur from any single failure including a wholly burnt

fire subdivision or flooded watertight compartment.

Table 1 gives an overview of the IMO dynamic positioning system classification system and the roughly corresponding dynamic positioning system class notations, individual variations exist.

Elements of ROV DP System

A typical ROV DP system is shown in Fig. 2. The components and their relevance are explained below.

The controller computes control forces based on the error between the desired position and the actual position. The desired position is derived from guidance software. The actual position is taken from the navigation system. Control forces must be transformed to thruster commands by thrust allocation matrix (Fossen and Johansen 2006) and then send to thrusters.

Thrusters provide DP capability for ROVs. Normally a DP ROV has an over-actuated vector thrust system. A single or multi failure of thrusters will not cause the system to fail according to the specific thruster configuration. Fault-tolerant control algorithms were proposed by researchers (Yang et al. 1998; Ni and Fuller 2003; Omerdic and Roberts 2004).

Navigation system indicates the position of ROVs. Ultra short base line (USBL), Doppler velocity log (DVL), or inertial measurement unit (IMU) is used to obtain position information. For some underwater application, integrated navigation combining the above sensors and pressure sensor, altimeter, digital compass, etc. is used to get a more accurate position. Raw data from sensors are processed in order to check for validity and consistency, and filtered by observers such as extended Kalman filter (EKF). The observer continues estimation of ROV status even if sensors fail to provide raw data, referred to as dead reckoning.

Environmental disturbances are mainly generated by ocean currents for ROV DP system. It's inconvenient to measure current forces. The traditional way is to design a robust controller or estimate current forces by an observer. Winds and waves can be neglected in underwater environment.

ROV Dynamic Positioning, Table 1 IMO DP classification

Description	IMO	Corresponding class notations					
	DP Class	ABS	LRS	DNV	GL	NK	BV
Manual position control and automatic heading control under specified maximum environmental conditions		DPS-0	DP (CM)	DPS0 DYNPOS-ATUS			
Automatic and manual position and heading control under specified maximum environmental conditions	Class1	DPS-1	DP (AM)	DPS 1 DYNPOS-AUT	DP1	DPS A	DYNAPOS AM/AT
Automatic and manual position and heading control under specified maximum environmental conditions, during and following any single fault excluding loss of a compartment (two independent computer systems)	Class2	DPS-2	DP (AA)	DPS 2 DYNPOS-AUTR	DP2	DPS B	DYNAPOS AM/AT R
Automatic and manual position and heading control under specified maximum environmental conditions, during and following any single fault including loss of a compartment due to fire or flood. (At least two independent computer systems with a separate backup system separated by A60 class division)	Class3	DPS-3	DP (AAA)	DPS 3 DYNPOS-AUTRO	DP3	DPS C	DYNAPOS AM/AT RS

ROV Dynamic Positioning, Fig. 2 Block diagram of ROV DP system

The desired position is derived from guidance software. Guidance software includes set-point regulation, trajectory tracking, and path following modules to accomplish different operations. Guidance software continuously computes the desired position according to predefined track or path. Guidance software can also take inputs from joysticks directly.

The ROV DP system comparing with ship DP system is listed in Table 2.

Scientific Problems to be Solved

It's hard to obtain a precise mathematical model of ROVs. The traditional way of modeling an ROV

is by computational fluid dynamics (CFD) and scaled model test. The mathematical model is just approximation in typical working condition.

Environmental disturbances are hard to be measured. There exists error in the estimation of environmental forces by observer. The error can be even more significant without a precise model of ROV. Besides, the forces from umbilical cable grow with water depth as a result of increasing cable length. Proper ways to measure or estimate disturbances need to be found.

ROV DP system needs to keep the station in both horizontal and vertical plane simultaneously, increasing complexity of the system. Robust

controller with good performance in hazardous underwater environment remains in laboratory. Performance of controller is affected by model accuracy, sensor configuration, and sea condition in practical application.

Application

Researchers from the Norwegian University of Science and Technology presented a dynamic positioning system for a small size ROV called Minerva in 2011 (Dukan et al. 2011), as shown in Fig. 3. Minerva is equipped with two horizontal

thrusters, two vertical thrusters, and one lateral thruster, accomplishing six degrees of motion. Navigation sensors consist of fluxgate compass, CRS03 silicon rate sensor, Teledyne RDI Workhorse Doppler velocity log (DVL), Kongsberg MRU6, and Kongsberg HiPAP500. The National Instruments (NI) CompactRIO (cRIO) programmed with LabVIEW is used for the implementation and development of the DP controller. Kalman filter (KF) and extended Kalman filter (EKF) are used as observer.

The DP system of Minerva consists of signal processing, observer, controller, guidance system, and thrust allocation modules as seen in Fig. 4.

ROV Dynamic Positioning, Table 2 Comparison with dynamic positioning of ships

	ROV DP	Ships DP
Control parameter	Horizontal position Vertical position Heading	Horizontal position Heading
Environmental disturbance	Ocean current	Wind Wave Ocean current
Navigation sensor	DVL USBL IMU Digital compass Pressure sensor	DGPS Gyrocompasses Environmental sensor
Propulsion	Thrusters	Main propellers Tunnel thrusters Azimuth thrusters

ROV Dynamic Positioning,
Fig. 3 Minerva ROV
(Dukan et al. 2011)

ROV Dynamic Positioning, Fig. 4 DP system of Minerva (Dukan et al. 2011)

ROV Dynamic Positioning, Fig. 5 Station keeping test of Minerva ROV DP system (Dukan et al. 2011)

ROV Dynamic Positioning, Fig. 6 Trajectory tracking test of Minerva ROV DP system (Dukan et al. 2011)

The signal processing module gathers signals from all sensors and checks validation of each signal data frame. Valid signals are passed to the observer module. Invalid signals are discarded and an abortion message is sent to observer module. The observer takes inputs from signal processing module and thrust allocation module. The outputs are estimated states of ROV. The controller module computes control force vector based on error between the desired states and estimated states. The thrust allocation module transforms control force vector to rotation speed of each thruster. The guidance module generates desired states for station keeping, trajectory tracking or path following.

Experimental results proved the validity and performance of the DP system. Result of the ROV DP system in station keeping test is shown in Fig. 5. The maximum measured deviation from desired position was 2 cm in North and 3 cm in East direction. The estimated deviation was within 2 cm in both North and East directions.

The results of trajectory tracking test are shown in Fig. 6. Maximum estimated cross-track error is 9 cm and measured is 20 cm.

Definition

The *safety* culture in the ocean engineering covers the safety of personnel, platform, and environment, and it is referred to the control of recognized hazards in order to achieve an acceptable level of risk.

Scientific Fundamentals

Introduction

In ocean engineering, the offshore engineering oil and gas industry is usually regarded as a high-risk sector, where the workers face not only process hazards associated with exploration, storage, and processing of hydrocarbons on the platforms but also other forms of hazards related to the harsh working environment and transportation (Broni-Bediako and Amorin 2010; Tang et al. 2017). It is generally agreed that the safety of offshore engineering can be grouped into two main categories, namely, personal safety and process safety (Swuste et al. 2016; Tang et al. 2018).

The personal safety emphasizes the health and safety of individual employees via minimization

of their exposure to radiations, chemical, noise, extreme vibration, abnormal temperatures, and mechanical, electrical, and ergonomic hazard with the measures such as industrial hygiene monitoring, chemical health risk assessment, medical surveillance, safety awareness program, and the work arrangement to reduce the fatigue of employee (International Labour Organization 2001; Mearns et al. 2003; Mearns and Hope 2005; Venkataraman 2008).

The process safety primarily concerns the hazards of offshore engineering related to the spills, fires, explosions, instability, capsizing, and destruction, which cause not only injuries and fatalities but property and environmental damage (Knegtering and Pasman 2009; Swuste et al. 2016). In many instances, the term process safety is usually interchangeable with asset integrity, where the asset integrity management usually covers the entire life cycle of an asset from design to decommissioning and includes management of processes, resources, people, and system (Hassan and Khan 2012).

The consequences of the process safety are usually potentially involving multiple injuries and fatalities, and they are more severe than those of the personal safety (Knegtering and Pasman 2009).

Typical Safety Issues in Offshore Engineering

Safety can be regarded as the absence of accidents or failures. The insight about safety features can be gained from detailed information of accidents

and failures. In the following, several typical catastrophic accidents in offshore engineering, which caused not only major economic and life losses but also serious environmental damage, are provided.

Structural Failure Due to the Extreme Environmental Loadings

Although the extreme environment condition occurs quite rarely during the life of offshore structure, the environmental loadings accompanied with this environment condition may exceed the design loading of offshore structure, and this may lead the structure into failure. As one of the extreme environment conditions, the hurricane with high storm surge and waves, heavy rains, and strong winds may have significant influence on the offshore structure.

The Hurricane Katrina entered the GOM on August 26, 2005. Prior to hurricane landfall, more than 700 platforms and rigs were evacuated making more than 90% of the oil and 83% of gas production in GOM offline (Feltus 2005). Statistical results have shown that the Hurricane Katrina completely destroyed 44 platforms and severely damaged 21 others (MMS 2006), including some large production facilities. The number of destroyed and severely damaged offshore platforms with different water depth is listed in Tables 1 and 2, respectively (Cruz and Krausmann 2008).

In addition, the drilling rigs were also affected. The hurricane destroyed four drilling rigs and severely damaged nine others, and six drilling rigs, including semisubmersible and jack-up units, were set adrift (Ghonheim and Colby 2005; Tubb 2005). In one case, a drilling rig (ENSCO 7500) was moved 193 km south of Louisiana, and Diamond's Ocean Warwick (75 m jack-up) was carried 106 km by the storm and washed up in Dauphin Island, Alabama. Furthermore, about 100 pipelines were damaged, and 36 of them were 0.254 m diameter or larger, and there were 211 minor pollution incidents of 500 barrels of oil or less in the outer continental shelf due to Katrina (MMS 2006).

In the same year, the Hurricane Rita entered the GOM on September 25, and it destroyed

Safety of Offshore Platforms, Table 1 Number of platforms destroyed by hurricanes Katrina and Rita

	Hurricane Katrina	Hurricane Rita
Water depth (m)	Number of destroyed	Number of destroyed
$d < 30$	16	30
$30 < d < 60$	14	27
$60 < d < 120$	14	11

Safety of Offshore Platforms, Table 2 Number of platforms damaged by hurricanes Katrina and Rita

	Hurricane Katrina	Hurricane Rita
Water depth (m)	Number of destroyed	Number of destroyed
$d < 60$	6	7
$60 < d < 120$	6	18
$120 < d < 240$	5	5
$300 < d < 1000$	4	2

69 platforms and 1 rig. There were 32 platforms severely damaged, and 13 rigs were set adrift by the Hurricane Rita (Djamarani 2005; MMS 2006). As was the case during Hurricane Katrina, the pipelines were also affected by Rita. The MMS reported that there were about 83 pipelines damaged, and 28 of them were 0.254 m diameter or larger, and 207 minor pollution incidents of 500 barrels of oil or less in the outer continental shelf due to Hurricane Rita (MMS 2006).

More than 2000 people lost their life in hurricanes Katrina and Rita. The direct economic losses were about \$70–130 billion, and the reconstruction costs were expected to reach about \$200 billion. Following the hurricanes, changes have been proposed to operating and emergency procedures, maintenance requirements, and design practices including mooring practices for mobile offshore drilling units (Cruz and Krausmann 2008).

Structural Capsizing Due to Fatigue Failure

The offshore structures are exposed to multiple sea states during their service life, which may cause seriously accumulative fatigue damage

Safety of Offshore Platforms, Fig. 1 Alexander L. Kielland platform capsized in 1980 due to the fatigue crack (Norwegian Petroleum Museum)

and lead the offshore structures to fatigue failure even if the stresses in the critical regions are smaller than the elastic limit (Jia 2008; Song and Wang 2019). The fatigue damage becomes a major cause of damages that occurred on the offshore structures.

As illustrated in Fig. 1a, the Alexander L. Kielland platform capsized while working in the Ekofisk oil field in March 27, 1980, and there were about 123 crews killed, making the capsize the worst disaster in Norwegian waters since World War II (Bunn 2018). The accident started with one of the bracings (D-6) failing due to fatigue, thereby causing a succession of failures of all bracings attached to this leg (see Fig. 1b). It was discovered during the investigation that the weld of an instrument connection on the bracing

had contained cracks, which had probably been in existence since rig was built. The cracks had developed over time, and the remaining steel was less than 50%, and the strength of the bracing did not meet the serviceability requirement of the platform.

When the leg came loose, the rig almost immediately developed a severe listing. Within 20 min of the initial failure, it capsized completely, floating upside down with just the bottom of the columns visible in the sea (see Fig. 1c). Both the escape and evacuation operations were far away from orderly and had only limited success. Only one lifeboat was in fact launched successfully, one was totally unavailable due to the listing, and others were smashed against the platform during launching in high waves.

Safety of Offshore Platforms, Fig. 2 Platforms destroyed by explosions and fires. (a) Piper Alpha platform accident in 1988, (b) P-36 semisubmersible platform accident in 2001 (Moan 2005)

Structural Destruction Due to Explosion and Fire
Due to the operational errors or technical faults, the oil and gas leaked from the equipment may be ignited, and the offshore structure can be destroyed by the explosions and fires (Moan 2005).

The Piper Alpha platform got explosions and fires in July 6, 1988, and it was one of the costliest man-made catastrophes ever occurred either onshore or offshore (Ian 2012). The explosions and fires were initiated by a gas leak from the blind flange of a condensation pump that was under maintenance but not adequately shut down (PA 1990). As presented in Fig. 2a, the Piper Alpha platform was completely destroyed by the explosions and fires. The accidents resulted in the loss of 167 crew members, including 2 crewmen of a rescue vessel, and the economic loss of about \$ 3.4 billion. The investigative report pointed out that the main issue that caused the initiation of this accident was the lack of communication between the maintenance team and the control room operations.

The Petrobras 36 (P-36), the largest floating semisubmersible platform in the world in that time, experienced two explosions in March 15, 2001. The accident was initiated by the rupture of the emergency drain tank in the starboard aft column due to excessive pressure, and the rupture caused damage to various equipment and installations, leading to the flooding of water, oil, and gas into the column. After 17 min, the dispersed gas caused explosion and fire. At the time there are 175 people on the

platform and 11 were killed. The platform sank 5 days after the explosion with an estimated 1700 t of crude oil remaining on board (Videiro et al. 2002). A series of operational errors were identified as the main cause of the first explosion and also the sinking.

Environmental Damage Resulted from Oil Spill

The oil spills accompanied with offshore engineering accidents have significant influence on the environment and ecosystem. In April 20, 2010, the Deepwater Horizon platform, which drilled the deepest oil well in history at a vertical depth of 10,683 m (see Fig. 3a), exploded and caught fire due to ignition of the high-pressure methane gas from the well (Schwartz and Weber 2010). There were 126 crew members on board when the platform caught fire, and 11 missing workers were believed to be dead from the explosion (see Fig. 3b).

The oil flowed for 87 days, and the total estimated volume of leaked oil approximated 4.9 million barrels with plus or minus 10% uncertainty, making it the world's largest accidental spill (Hoch 2010). According to the satellite images, the spill directly affected 68,000 square miles of the ocean (see Fig. 3c) and had affected 8332 species, including more than 1270 fish, 604 polychaetes, 218 birds, 1456 mollusks, 1503 crustaceans, 4 sea turtles, and 29 marine mammals (Biello 2010; Norse and Amos 2013).

Research found that the toxins from oil spills can cause irregular heartbeats leading to cardiac arrest and the tuna and amberjack that were

Safety of Offshore Platforms, Fig. 3 Deepwater Horizon oil spill (<https://en.wikipedia.org>)

exposed to oil from the spill developed deformities of the heart and other organs that would be expected to be fatal or at least life-shortening (Kerr 2010). In addition, the spill had a strong economic impact to BP and also the Gulf Coast's economy sectors such as offshore drilling, fishing, and tourism. Estimates of lost tourism dollars were projected to cost the Gulf coastal economy up to 22.7 billion through 2017. The GOM commercial fishing industry was estimated to have lost \$ 247 million as a result of post-spill fisheries closures (Sumaila et al. 2012). BP may be required to pay as high as \$ 90 billion.

Key Applications

Safety Design

Design Criteria

Safety design is referred as the design that effectively minimizes the likelihood of accidents/

damages and mitigates their consequences, which has long been a priority in the offshore engineering industries. As uncertainties in the structural resistance and the environmental loads to the structures for all kinds of reasons, the design approaches can be grouped into two main categories, namely the deterministic design approach and the probability design approach.

Deterministic Design Method

The deterministic design method, which is also known as working stress design (WSD) method, assumes that all kinds of environmental loadings are combined, and it may fit a certain probability distribution, and the resistance of structure is deterministic. In the design process, the stress of the structure under different environmental loadings should be less than the allowable stress, and a global safety factor is used to quantifying uncertainties of environmental load and structural capacity.

The deterministic design method is mainly considered as applicable to special case design problems, to calibrate the usage factors to be used in the WSD method and for conditions where limited experience exists. The detail of the deterministic design method can be found in API RP 2A (2000) for fixed platform and DNV-OS-C201 (2015) for floating platform.

Probabilistic Design Method

The probabilistic design method which is also known as load and resistance factor design (LRFD) method assumes that all kinds of environmental loads fit different probability distributions and the structural resistance/capacity is probabilistic and also obeys a certain distribution function as well. According to the probabilistic design method, the target safety level of the structure is obtained as closely as possible by applying load and resistance factors to characteristic reference values of the basic variables.

The basic variables are defined as loads acting on the structure and the resistance of the structure or the resistance of materials in the structure. The target safety level is achieved by using deterministic factors representing the variation in load and resistance and the reduced probabilities that various loads will act simultaneously at their characteristic values. The details of the probabilistic design method can be found in DNV-OS-C101 (2011).

Safety Assessment and Management

General

The offshore platforms are systems consisting of structures, equipment, and other hardware, as well as specified operational procedures and operational personnel. Ideally, the system should be designed and operated to comply with a certain acceptable risk level as specified. The safety assessment and management is the process to ensure that the risks of offshore platform are reduced to a level as low as reasonably practicable via hazard identification, risk assessment, and monitoring (Gupta and Edwards 2002). Typical elements of a safety assessment and management process consist of data collection and

management, risk assessment, inspection and monitoring plan, and strengthening and mitigation measures (International Labour Organization 2001; Li et al. 2012).

Data Collection and Management

The data of offshore structure is the foundation of safety assessment and management process, and it can be grouped into two main categories, namely, characteristic data and condition data.

1. Characteristic data: the data represents the structure's characteristic in initial condition, and it relates to the structure design, fabrication, transportation, and installation process, including the design drawing, analysis results, fabrication planning, transportation and installation report, and other related files.
2. Condition data: the data represents the structure's characteristics in operation condition, including the inspection data, monitoring data, maintenance and repair report, etc.
3. An effective data management system should be established to save, modify, and update the related data.

Safety Assessment

The safety assessment of offshore platforms during operation is necessary in connection with a planned change of platform function; extension of service life; occurrence of overload damage due to hurricanes, explosion, fires, and ship impact; updating of inspection plans; etc. (Moan 2005). The safety assessment should be based on updated data of offshore structure, and the corresponding results can be represented by the safety indicators, which can measure the safety performance of the offshore structure and provide input for the planning of inspection, monitoring, maintenance, and repairs. The procedure of safety assessment is illustrated in Fig. 4.

Inspection and Monitoring Planning

Inspection and monitoring are important measures for maintaining safety, especially with respect to fatigue, corrosion, and other deterioration phenomena. The inspection and monitoring data of a

Safety of Offshore Platforms, Fig. 4 The procedures of the safety assessment (Li et al. 2012)

given structure is actively incorporated in the planning of future activities (Moan 2005).

The inspection planning is usually formulated based on the results of safety assessment, which is the overall and strategic arrangement of platform inspection, including the inspection intervals and scope. Typically, the major inspections of offshore structures are carried every 4–5 years, while intermediate and annual inspections are normally less extensive. The optimal inspection interval can be determined with the probabilistic methods.

The following items should be included in the inspection planning:

1. Prioritizing which locations are to be inspected.
2. Selection inspection method (visual inspection, magnet particle inspection, eddy current) depending on the damage of concern.
3. Scheduling inspections.

4. Establishing a repair strategy (size of damage to be repaired, repair method, and time aspects of repair).

Strengthening and Mitigation Measures

If the safety of offshore structure did not meet the serviceability and safety requirements, some strengthening and mitigation measures should be carried out to strengthen and mitigate the structure. The permanent repairs are made by cutting out component and welding a new component, rewelding, and adding or removing scantlings, brackets, stiffeners, lugs, or collar plates.

However, the strengthening and mitigation measures are usually very expensive. The most relevant measure to alleviate the intensity of repair could be achieved by varying the inspection interval or improving the inspection technology. Many approaches regarding the repair cost as a criterion in reliability-based inspection, monitoring, maintenance, and repair planning have been developed

(Garbatov and Guedes Soares 2001; Moan 2005; Dong and Frangopol 2015).

It should be mentioned that the risk can never be absence, and the implementation of the safety assessment and management never ends, and it should be carried out through the life cycle of offshore structure.

Conclusions

The offshore engineering oil and gas industry has large investment and long-period and high-risk features, and the failure of the offshore facilities usually resulted in the loss of economy and life and subsequent pollution of the environment. Safety is a very important characteristic of the offshore engineering oil and gas industry, and it can be ensured by improving the design method and reducing the human and organizational errors and omissions.

The safety assessment and management process is a scientific management strategy to identify, measure, and analyze risk and, on this basis to deal effectively with risk, to achieve maximum security at minimum cost. In the future, the safety assessment and management process can be established with multiple data sources and advanced methods to account for complex interactions between the natural environment, the development of naval technology, and human behavior.

Salinity Gradient Power Conversion

Zhen Gao

Norwegian University of Science and Technology, Trondheim, Norway

Synonyms

SGPC - salinity gradient power conversion; PRO - pressure-retarded osmosis; RED - reverse electro-dialysis; AEM - anion-exchange membrane; CEM - cation-exchange membrane

Definition

Salinity gradient power is the power available from the difference in the salt concentration between sea water and river fresh water and it is often called osmotic power or blue energy. This form of power is available when two solutions with different salinity levels are mixed together. Salinity Gradient Power Conversion (SGPC) is a technology that uses the osmotic pressure, i.e., the chemical potential of concentrated and dilute solutions of salt, to drive a turbine to generate electricity.

Salinity Gradient Power Resource

In order to utilize the salinity gradient power, a large amount of both sea water and fresh water are needed. River mouths, where fresh river water discharges to the sea, are naturally potential areas for SGPC development and are widely distributed around the world (Lewis et al. 2011). The estimated technical potential for SGPC is about 1650 TWh/year (Scråmestø et al. 2009).

Technology for Salinity Gradient Power Conversion

Like ocean thermal energy, salinity gradient power is less developed than any other ocean

energy. No commercial plant based on salinity gradient power and only a few pilot plants exist today.

From the technology point of view, there are two types of SGPC, namely, Pressure-Retarded Osmosis (PRO) and Reverse Electrodialysis (RED), as shown in Fig. 1. In a PRO plant

(Scråmestø et al. 2009), both fresh water and sea water are pumped in two different loops to a chamber where semi-permeable membranes are placed between them and permit only water molecules to pass through. Water flows from the dilute solution (fresh water) to the concentrated solution (sea water) to bring the chemical potentials on

Salinity Gradient Power Conversion, Fig. 1 Illustration of PRO (left, Scråmestø et al. 2009) and RED (right, van den Ende and Groeman 2007) for ocean salinity gradient conversion

both sides of the membranes to an equilibrium, which will lead to high pressure on the sea water side and then drive a turbine to generate electricity. The osmotic pressure between sea water and fresh water is in the order of 2.4–2.6 MPa. The sea water is pressurized to about half of the osmotic pressure, before pumped into the chamber. As long as the pressure difference at the membranes between the two fluids is less than the osmotic pressure, the flows from fresh water to sea water continue. The remaining fresh water and the mixed fresh and sea water are then discharged to the river or the sea.

The RED approach (van den Ende and Groeman 2007) is essentially to create a salt battery, using ion-exchange membranes, which either let negatively charged ions in anion-exchange membranes (AEM) or positively charged ions in cation-exchange membranes (CEM) pass through. These AEM and CEM membranes are alternately stacked with water-based solutions of different concentrations in between to build up a considerable electrical potential that can be used for electricity generation.

Development and Challenges for Salinity Gradient Power Conversion

The concepts of PRO and RED have been proposed in 1970s. However, it is in 2009 that the first PRO power plant with a nominal power of 10 kW was built and started operation by the Norwegian company Statkraft. It uses about 2000 m² of membranes to eventually generate 5 kW of electric power (IRENA 2014). In 2014, the first RED plant with a nominal power of 50 kW was built at Afsluitdijk, the Netherlands, using the fresh water from Lake IJssel and the sea water of the North Sea (Schaetzle and Buisman 2015).

The developed prototypes of SGPC devices are very small, with a cost not competitive to other forms of ocean renewable energies. There exist many technical challenges for SGPC devices (Schaetzle and Buisman 2015). Both PRO and RED need a large amount of fresh and sea water, which should be pumped into specific chambers. This requires a large facility and increases the

overall cost. Both PRO and RED plants use membranes, which are very sensitive to fouling, i.e., the accumulation of minerals or marine growth on the membranes and require very clean water. This is a challenge in real world. In the case of a RED plant, the ion composition of the real fresh and sea water is much more complex than that is assumed in the lab tests with simple NaCl solutions. This will make the efficiency of a RED plant lower.

Second Generation Intact Stability Criteria

Min Gu, Jiang Lu, Shuxia Bu, Jilong Chu,
Ke Zeng and Tianhua Wang
China Ship Scientific Research Center (CSSRC),
Wuxi, China

Definition

Interim guidelines on the second generation intact stability criteria are approved by the International Maritime Organization (IMO) on 10 December 2020, and IMO Member States are invited to use the interim guidelines as complementary measures when applying the requirements of the mandatory criteria of part A of the International Code on Intact Stability, 2008 (resolution MSC.267(85)), and to bring them to the attention of all parties concerned, in particular shipbuilders, shipmasters, shipowners, ship operators, and shipping companies, and recount their experiences gained through the trial use of these interim guidelines to the organization. The second generation intact stability criteria include five stability failure modes as follows: dead ship condition, excessive acceleration, pure loss of stability, parametric rolling, and surf-riding/broaching with Level 1, Level 2 vulnerability criteria, and direct stability assessment for each stability failure model. The main purpose of these criteria is to enable the use of the latest numerical simulation techniques for evaluating the safety level of a ship from an intact stability viewpoint (IMO, Msc.1/Circ.1627, 2020).

Historical Development

The IMO intact stability criteria (resolution A.749(18)) were developed based on the

experience with ships designed and built quite some years ago – in the 1930s, and the empirical criteria do not and cannot represent the physical properties of modern vessels and a set of performance-based criteria is proposed to be developed (Germany, IMO SLF 45/6/2, 2002).

The intact stability code applies to all ships based on two different concepts: general criteria addressing the geometry of the calm water lever arm curve and the weather criterion consisting of a set of empirical formulae. The weather criterion is only based on beam wind and beam waves scenario, and the other stability failure models in quartering, following, and head seas cannot be included. Due to the restriction to the static calm water lever arm curve, dynamic problems endangering ships cannot be assessed. The scenario-based criteria including parametric rolling, pure loss of stability, and excessive acceleration in case of resonance are proposed to be developed (Germany, IMO SLF 46/6/6, 2003). A long-term approach should cover dynamic criteria (Germany, IMO SLF 46/6, 2003).

The development of dynamic stability criteria may have the following structure: criteria to avoid large rolling angles (minimum stability requirement), criteria to avoid large acceleration (maximum stability limit), criteria to guarantee sufficient roll damping in dead ship condition (minimum damping requirement), and criteria to avoid broaching (minimum course keeping limit) (Germany, IMO SLF 47/6/4, 2004).

The working group on the review of the intact stability code agreed that for three identified phenomena, i.e., pure loss and parametric excitation, behavior in dead ship condition and maneuvering-related problems (e.g., broaching-to), and necessary preliminary precautionary provisions should be in the code (as new paragraph 1.2 of part A of the draft revised Code) (Germany, SLF 48/4/7, 2005; SLF 48/WP.2, 2005).

In order to back up the long-term work tasks, Germany further gave out a proposal of probabilistic intact stability criterion (Germany, SLF 49/5/2, 2006), and Japan gave out proposals on the methodology of direct assessment for stability under dead ship condition and capsizing due to broaching (Japan, SLF 49/5/5, 49/5/6, 2006).

Japan, the Netherlands, and the USA believe that the motivation for the development of performance-based criteria for intact stability is derived from the appearance of new types of vessels. These vessels may have unconventional hull particulars or geometry or modes of operation for which there is insufficient operational experience. Performance-based criteria should be applicable to unconventional vessels while the existing intact stability code still be applicable to “conventional” vessels. The performance-based criteria also could be used as an alternative procedure for “conventional” vessels. A framework for the development of new generation criteria for intact stability is proposed by Japan, the Netherlands, and the USA, and parametric rolling, pure loss of stability, stability under dead ship condition, and broaching-to are considered (SLF 50/4/4, 2007).

The new generation intact stability criteria will be applicable to unconventional types of ships, assessed by vulnerability criteria (Germany, SLF 51/4/1, 2008). Japan gave out a proposal of new generation intact stability criteria as an example (Japan, SLF 51/4/3, 2008). The working group agreed to the framework for the new generation intact stability criteria and the draft terminology for the new generation intact stability criteria (SLF 51/WP.2, 2008).

In considering the best way forward on the necessary work for the new generation intact stability criteria, the working group, based on the report of the correspondence group (SLF 52/3/1, 2009 and SLF 52/INF.2, 2009), taking into account the relevant documents submitted to this session, developed a summary of methodology considered for the stability failure modes. The framework of the new generation stability criteria is confirmed including Level 1, Level 2 vulnerability criteria, direct stability assessment, and operational guidance for stability failure models, and the stability failure modes include pure loss of stability, parametric rolling, surf-riding/broaching, and dead ship condition (SLF 52/WP.1, 2010).

The name of “the new generation intact stability criteria” is changed as “the second generation intact stability criteria” in the conference SLF 53, and the structure of the second generation

intact stability criteria is updated with five stability failure models such as pure loss of stability, parametric roll, surf-riding/broaching, dead ship condition, and excessive acceleration, and each failure model has multiple levels including Level 1, Level 2 vulnerability criteria, direct stability assessment, and operational guidance (SLF 53/WP.4, 2011).

Following an in-depth discussion, the working group prepared an updated version of the draft vulnerability criteria of Level 1 and 2 for pure loss of stability, parametric roll, dead ship, and surf-riding/broaching (SLF 54/WP.3, 2012).

The working group prepared a revised plan, identifying the priorities, time frames, and objectives for the work to be accomplished. The working group agreed on the draft vulnerability criteria of Levels 1 and 2 for the failure mode parametric roll, and agreed to the selection of a wave environment for the first and second level vulnerability criteria for parametric rolling. The working group discussed the direct assessment methodologies considering their importance for ships which fail vulnerability levels 1 and 2 and to develop operational guidance when necessary (SLF 55/WP.3, 2013).

Subcommittee of ship design and construction (SDC) is established including the working of subcommittee on stability and load lines and on fishing vessels safety. The working group reviewed the second generation intact stability criteria on the base of the correspondence group and prepared a revised plan, identifying the priorities, time frames, and objectives for the work to be accomplished (SDC 1/WP.5, 2014).

The working group finalized the draft amendment to the 2008 Intact Stability Code regarding vulnerability criteria and the standards of levels 1 and 2, and further developed the direct stability assessment procedures (level 3) for the five stability failure models. The working group was the view that each criterion should have a single option. On the other hand, the working group was also of the view that the calculation of some parameters may include different options (SDC 2/WP.4, 2015).

For the finalization of the second generation intact stability criteria, the working group further

considered the draft criteria in levels 1 and 2 for the five stability failure modes, further developed the draft explanatory notes for all five failure modes, and further developed the draft guidelines of direct stability assessment procedures and operational limitation/guidance (SDC 3/WP.5, 2016).

The working group further considered the draft criteria in levels 1 and 2 for the five stability failure modes, further developed the draft guideline for the specification of direct stability assessment with a view to preparing draft interim guidelines, further developed the draft explanatory notes for all five failure modes with a view completing the draft interim explanatory notes, and further developed the draft guidelines for the preparation and approval of operation limitation and operational guidance with a view to preparing draft interim guidelines (SDC 4/WP.4, 2017).

A provisional work plan was drafted with a view to ensuring the finalization of the second generation of intact stability criteria (SDC 5/J.6, 2018).

With a view to presenting outcomes ready for finalization, continued progress made by the experts' group on intact stability including the draft interim guidelines on the specification of direct stability assessment procedures, the draft interim guidelines for the preparation of operational limitation and operational guidance, and the draft interim guidelines on vulnerability criteria for the second generation of intact stability criteria (SDC 6/WP.6, 2019).

The draft group on intact stability discussed the best possible method of work to finalize the draft interim guidelines on the second generation intact stability criteria and agree to elaborate on the matters pending in square brackets as a matter of priority, followed by a complete editorial review of the draft guidelines. The draft group agreed to remove all references to the draft explanatory note (SDC 7/WP.6, 2020).

Interim guidelines on the second generation intact stability criteria is approved by the International Maritime Organization (IMO) on 10 December 2020 (IMO, Msc.1/Circ.1627, 2020).

The explanatory note is under discussion by the correspondence group of the second

generation intact stability criteria and will be submitted to SDC 8 (Jan., 2022).

Application Logic

Figure 1 shows the simplified scheme of the application structure of the second generation intact stability criteria. As the simplest options, the vulnerability criteria are presented in two levels: Level 1 and Level 2. The assessment of the five stability failure modes should begin with the use of these levels. Level 1 is an initial check and then, if the ship in a particular loading condition is assessed as not vulnerable for the tested failure mode, the assessment for that failure mode may conclude, otherwise the design would progress to Level 2. If the ship in a particular loading condition is assessed as not vulnerable for the tested failure mode in Level 2, then the assessment would conclude, otherwise the design would progress to the application of direct stability assessment, application of operational limitations, revising the design of the ship, or discarding the loading condition. If the ship in a particular loading condition is not found acceptable with respect to direct stability assessment procedures, then the logic is that the design would then

progress to the application of operational measures or operational guidance, revising the design or discarding the loading condition (IMO, Msc.1/Circ.1627, 2020).

Vulnerability Criteria of Five Stability Failure Modes

Parametric Rolling

Parametric rolling is a dynamic stability phenomenon in which an amplification of roll motion is caused by periodic variation of transverse stability in waves. The vulnerability criteria of parametric rolling are shown as follows.

Level 1 Vulnerability Criteria of Parametric Rolling

For each loading condition a ship is considered not to be vulnerable to the parametric rolling failure mode if

$$\frac{\delta GM_1}{GM} \leq R_{PR} \quad \text{and} \quad \frac{V_D - V}{A_W(D - d)} \geq 1.0 \quad (1)$$

In which $R_{PR} = 1.87$ if the ship has a sharp bilge and otherwise:

Second Generation Intact Stability Criteria, Fig. 1 Simplified scheme of the application structure of the second generation intact stability criteria. (IMO, Msc.1/Circ.1627, 2020)

$$\begin{cases} R_{PR} = 0.17 + 0.425 \left(\frac{100A_k}{LB} \right), & \text{if } C_{m,\text{full}} > 0.96; \\ R_{PR} = 0.17 + (10.625 \times C_{m,\text{full}} - 9.775) \left(\frac{100A_k}{LB} \right), & \text{if } 0.94 \leq C_{m,\text{full}} \leq 0.96; \\ R_{PR} = 0.17 + 0.2125 \left(\frac{100A_k}{LB} \right), & \text{if } C_{m,\text{full}} < 0.94; \end{cases} \quad (2)$$

$\left(\frac{100A_k}{LB} \right)$ should not exceed 4; δGM_1 is amplitude of the variation of the metacentric height (m) calculated by Eq. (3), and $S_W = 0.0167$.

$$\delta GM_1 = \frac{I_{TH} - I_{TL}}{2V} \quad (3)$$

where I_{TH} , I_{TL} are transverse moment of inertia of the waterplane at the draft d_H (m) and transverse moment of inertia of the waterplane at the draft d_L (m).

$$\begin{aligned} d_H &= d + \delta d_H \\ d_L &= d - \delta d_L \\ \delta d_H &= \text{Min} \left(D - d, \frac{L \cdot S_W}{2} \right) \\ \delta d_L &= \text{Min} \left(d - 0.25d_{\text{full}}, \frac{L \cdot S_W}{2} \right) \end{aligned} \quad (4)$$

Level 2 Vulnerability Criteria of Parametric Rolling
For each condition of loading a ship is considered not to be vulnerable to parametric rolling if

$$\begin{aligned} C1 &\leq R_{PR1} = 0.06 \text{ or} \\ C2 &\leq R_{PR1} = 0.025 \end{aligned} \quad (5)$$

The value for $C1$ is calculated as a weighted average from a set of waves specified in (IMO, Msc.1/Circ.1627,2020).

$$C1 = \sum_{i=1}^N W_i C_i \quad (6)$$

In which W_i is weighting factor according to the wave data specified in (IMO, Msc.1/Circ.1627,2020).

If the Eq. (7) is satisfied, $C_i = 0$, otherwise $C_i = 1$.

$$\begin{aligned} &\left(GM(H_i, \lambda_i) > 0 \text{ and } \frac{\delta GM(H_i, \lambda_i)}{GM(H_i, \lambda_i)} < R_{PR} \right) \\ \text{or } &\left(\text{when } GM(H_i, \lambda_i) > 0, V_{PRi} = \left| \frac{2\pi_i}{T_r} \cdot \sqrt{\frac{GM(H_i, \lambda_i)}{GM}} - \sqrt{g \frac{\lambda_i}{2\pi}} \right| > V_s \right) \end{aligned} \quad (7)$$

The value for $C2$ is calculated as a weighted average from a set of waves conditions specified in (IMO, Msc.1/Circ.1627,2020)

$$C2(Fn_i, \beta) = \sum_{i=1}^N W_i C_{S,i} \quad (9)$$

$C2 =$

$$\left[\sum_{i=1}^{12} C2(Fn_i, \beta_h) + \frac{1}{2} (C2(0, \beta_h) + C2(0, \beta_f)) + \sum_{i=1}^{12} C2(Fn_i, \beta_f) \right] / 25 \quad (8)$$

$C2(Fn_i, \beta)$ can be calculated by Eq. (9).

In which W_i is weighting factor for respective wave cases specified in (IMO, Msc.1/Circ.1627,2020). Also, N is total number of wave cases for which the maximum roll angle is evaluated for a combination of speed and ship heading; C_i is 1 if the maximum roll angle in head and following waves according to one degree of rolling motion exceed 25 and 0 otherwise.

Pure Loss of Stability

The provisions given hereunder apply to all ships, except for ships with an extended low weather deck, for which the Froude number, Fn , corresponding to the service speed exceeds 0.24.

Level 1 Vulnerability Criteria of Parametric Rolling

For each loading condition a ship is considered not to be vulnerable to the pure loss of stability failure mode if

$$GM_{\min} \geq R_{PLA} \quad \text{and} \quad \frac{V_D - V}{A_W(D - d)} \geq 1.0 \quad (10)$$

where $R_{PLA} = 0.05$; GM_{mi} is minimum value of the metacentric height (m) calculated as provided in Eq. (11); $S_W = 0.0334$.

$$GM_{\min} = KB + \frac{I_{TL}}{\nabla} - KG \quad (11)$$

I_{TL} are transverse moment of inertia of the waterplane at the draft d_L (m).

$$d_L = d - \delta d_L$$

$$\delta d_L = \text{Min} \left(d - 0.25d_{\text{full}}, \quad \frac{L \cdot S_W}{2} \right) \quad (12)$$

KB : height of ship buoyance; KG : height of ship gravity; ∇ : displacement (m^3).

Level 2 Vulnerability Criteria of Parametric Rolling

For each condition of loading a ship is considered not to be vulnerable to pure loss of stability if

$$\max (CR_1, CR_2) \leq R_{PL0} = 0.06 \quad (13)$$

Each of the two criteria, CR_1 and CR_2 in 2.4.3.1, represents a weighted average of certain stability parameters for a ship considered to be statically positioned in waves of defined height, H_i , and length, λ_i , obtained according to (IMO, Msc.1/Circ.1627,2020). CR_1 and CR_2 are calculated as follows:

$$CR_1 = \sum_{i=1}^N W_i C1_i; \quad (14)$$

$$CR_2 = \sum_{i=1}^N W_i C2_i;$$

In which W_i is weighting factor for respective wave cases specified in (IMO, Msc.1/Circ.1627,2020). Also, $C1_i$ and $C2_i$ are calculated as follows:

$$C1_i = \begin{cases} 1 & \varphi_V < K_{PL1} = 30^\circ \\ 0 & \text{otherwise} \end{cases}$$

$$C2_i = \begin{cases} 1 & \begin{matrix} \varphi_{sw} > K_{PL2} \\ K_{PL2} = 15^\circ \text{ for passenger ships} \\ K_{PL2} = 25^\circ \text{ for other ships} \end{matrix} \\ 0 & \text{otherwise} \end{cases} \quad (15)$$

In which φ_v and φ_{sw} are angle of vanishing stability and angle of heel under action of heeling lever $l_{PL2} = 8(H_i/\lambda)dF_N^2$ specified in (IMO, Msc.1/Circ.1627,2020).

Surf-Riding/Broaching

Broaching is a violent uncontrollable turn that occurs despite maximum steering efforts to maintain course. As with any other sharp turn event, broaching is accompanied with a large heel angle, which has the potential effect of a partial or total stability failure. Broaching is usually preceded by surf-riding which occurs when a wave, approaching from the stern, captures a ship and accelerates the ship to the speed of the wave. Surf-riding is a single wave event in which the wave profile does not vary relative to the ship. Because most ships are directionally unstable in the surf-riding condition, this maneuvering yaw instability leads to an uncontrollable turn – termed “broaching” (SDC 3/WP.5/Annex 5, 2016). Broaching is considered as one of the most dangerous phenomena in following and stern-quartering waves for high-speed ships, such as destroyers and fishing vessels.

Level 1 Vulnerability Criteria of Surf-Riding/Broaching

For each loading condition a ship is considered not to be vulnerable to the surf-riding/broaching failure mode if

$$L \geq 200\text{m} \quad \text{or} \quad Fn \leq 0.3 \quad (16)$$

In which Fn is Froude number corresponding to ship service speed; L is ship length.

Level 2 Vulnerability Criteria of Surf-Riding/Broaching

For each loading condition a ship is considered not to be vulnerable to the surf-riding/broaching failure mode if

$$C = \sum_{H_s} \sum_{T_z} \left(W2(H_s, T_z) \sum_{i=0}^{N_\lambda} \sum_{j=0}^{N_a} w_{ij} C2_{ij} \right) < R_{SR} = 0.005 \quad (17)$$

Where $W2(H_s, T_z)$ is weighting factor of short-term sea state as a function of significant wave height H_s and zero crossing wave period T_z . Also w_{ij} is statistical weight of a wave with steepness $(H/\lambda)_i$ and wave length to ship length ratio $(\lambda/L)_i$ calculated with the joint distribution of local wave steepness and lengths. Finally, $C2_{ij}$ is a coefficient depends on ship propulsion and resistance characteristics as follows:

In which $N_\lambda = 80$, $N_a = 100$.

$$w_{ij} = 4 \frac{\sqrt{g} L^{5/2} T_{01}}{\pi v (H_s)^3} s_j^2 r_i^{3/2} \left(\frac{\sqrt{1+v^2}}{1+\sqrt{1+v^2}} \right) \Delta r \Delta s \cdot \exp \left[-2 \left(\frac{L \cdot r_i \cdot s_j}{H_s} \right)^2 \left\{ 1 + \frac{1}{v^2} \left(1 - \sqrt{\frac{g T_{01}^2}{2 \pi r_i L}} \right)^2 \right\} \right] \quad (18)$$

In which, $v = 0.425$; $T_{01} = 1.086 T_z$; $s_j = (H/\lambda)_j$, varying from 0.03 to 0.15 with increment $\Delta s = 0.0012$; $r_i = (\lambda/L)_i$, varying from 1.0 to 3.0 with increment $\Delta r = 0.025$.

The value of $C2_{ij}$ is calculated for each wave, as follows:

$$C2_{ij} = \begin{cases} 1 & \text{if } Fn > Fn_{cr}(r_i, s_j) \\ 0 & \text{if } Fn \leq Fn_{cr}(r_i, s_j) \end{cases} \quad (19)$$

$Fn_{cr} = u_{cr}/\sqrt{Lg}$ is critical Froude number corresponding to the threshold of surf-riding (surf-riding occurring under any initial condition) which should be calculated for the regular wave with steepness s_j and wavelength to ship length ratio r_i .

The critical nominal ship speed, u_{cr} , is determined by solving the following equation with the critical propulsor revolutions, n_{cr} :

$$T_e(u_{cr}; n_{cr}) - R(u_{cr}) = 0 \quad (20)$$

The critical propulsor revolutions, n_{cr} , is determined by solving the following equation in (IMO, Msc.1/Circ.1627,2020)

$$2\pi \frac{T_e(c_i; n_{cr}) - R(c_i)}{f_{ij}} + 8a_0 n_{cr} + 8a_1 - 4\pi a_2 + \frac{64}{3} a_3 - 12\pi a_4 + \frac{1024}{15} a_5 = 0 \quad (21)$$

Dead Ship Condition

Level 1 Vulnerability Criteria of Dead Ship Condition

For each loading condition a ship is considered not to be vulnerable to the dead ship condition failure mode if

$$b \geq a \quad (22)$$

In which, a and b are calculated according to 2008 IS Code Part A-2.3, and MSC.1/Circ.1200 Table 4.5.1.

Level 2 Vulnerability Criteria of Dead Ship Condition

For each loading condition a ship is considered not to be vulnerable to the dead ship condition failure mode if

$$C = \sum_{i=1}^N W_i(H_S, T_Z) \times C_{S,i}(H_S, T_Z) \leq R_{DS0} = 0.06 \quad (23)$$

In which, W_i is weighting factor of short-term sea state as a function of significant wave height H_S and zero crossing wave period T_Z .

$C_{S,i}$ is short-term dead ship stability failure index for the short-term environmental condition under consideration, calculated as specified in (IMO, Msc.1/Circ.1627,2020). N is total number of short-term environmental conditions.

$$C_{S,i} = 1, \text{ if either :} \\ \begin{aligned} &.1, \text{ the mean wind heeling lever } -l_{\text{wind,tot}} \text{ exceeds the righting lever, } GZ, \text{ at each heel to leeward, or} \\ &.2, \text{ the stable angle under the action of steady wind, } \varphi_S, \text{ is greater than the angle of failure to leeward, } \varphi_{\text{fail,+}}, \text{ and} \\ &= 1 - \exp(-r_{EA}T_{\text{exp}}), \text{ otherwise} \end{aligned} \quad (24)$$

Excessive Accelerations

When a ship is rolling, the objects in higher locations travel longer distances. A period of roll motions is the same for all the location onboard the ship. To cover longer distance during the same time, the linear velocity must be larger. As the velocity changes its direction every half a period, larger linear velocity leads to larger linear accelerations. Large linear acceleration means larger inertial force (SDC 3/WP.5/Annex 7, 2016).

Level 1 Vulnerability Criteria of Excessive Acceleration

For each loading condition a ship is considered not to be vulnerable to the excessive acceleration failure mode if

$$\varphi k_L (g + 4\pi^2 h_r / T_r^2) \leq R_{EA1} = 4.64 \text{ (m/s}^2\text{)} \quad (25)$$

In which φ is characteristic roll amplitude (rad) calculated by Eq. (26); k_L is factor taking into account simultaneous action of roll, yaw, and pitch motions; g is gravity acceleration; h_r is height above the assumed roll axis of the location where passengers or crew may be present (m), for

which definition, the roll axis may be assumed to be located at the midpoint between the waterline and the vertical center of gravity; and T_r is natural roll period.

$$\varphi = 4.43rs/\delta_\varphi^{0.5} \quad (26)$$

In which, r is effective wave slope coefficient; s is wave steepness as a function of the natural roll period T_r as determined in (IMO, Msc.1/Circ.1627,2020); and δ_φ is nondimensional logarithmic decrement of roll decay.

Level 2 Vulnerability Criteria of Excessive Acceleration

For each loading condition a ship is considered not to be vulnerable to the excessive acceleration failure mode if

$$C = \sum_{i=1}^N W_i C_{S,i} \leq R_{EA2} = 0.00039 \quad (27)$$

In which, long-term probability index measures the vulnerability of the ship to a stability failure due to excessive acceleration for the loading condition and location under consideration based on the probability of occurrence of short-

term environmental conditions, as specified in (IMO, Msc.1/Circ.1627,2020); W_i is weighting factor for the short-term environmental condition; and $C_{S,I}$ is short-term excessive acceleration failure index for the short-term environmental condition under consideration, calculated by Eq. (28).

$$C_{S,i} = \exp \left[-R_2^2 / (2\sigma_{Lai}^2) \right] \quad (28)$$

In which, $R_2 = 9.81 \text{ (m/s}^2\text{)}$; σ_{Lai} is standard deviation of the lateral acceleration at zero speed and in a beam seaway.

Synonyms

CUSS I (Continental, Union, Superior and Shell Oil Companies' Project Mohole); DP (dynamic positioning); LFC (low-frequency cycle); VIM (vortex-induced motion)

Definition

A **semi-submersible platform** is a specialized offshore unit used in a number of specific offshore roles such as drilling rigs, safety vessels, oil production platforms, and heavy lift cranes. They are designed with good stability and seakeeping characteristics. Other terms include semi-submersible, semi-sub, or semi for simplification (https://en.wikipedia.org/wiki/Semi-submersible_platform).

Introduction

Offshore drilling in water depth greater than 500 meters normally requires that operations be carried out from a floating vessel, as the cost on fixed structures are normally unaffordable. Initially in the early 1950s, monohull ships such as CUSS I (Keuren and David 2004) were used, but these were found to have significant heave, pitch, and yaw motions in large waves, and the industry needed more stable drilling platforms. Thus, semi-submersible platform concept came into engineering application soon (Fig. 1).

A semi-submersible platform, also known as the column stable drilling platform, which operates mainly in the deepwater area, is a floating production system that enables the drilling and exploitation of offshore oil and gas resource. Most of the floating body is below the water

Semi-submersible Platform, Fig. 1 North Dragon semi-submersible platform

surface, and the general positioning system is mooring lines, anchoring equipment, and dynamic positioning system (DP). Nowadays, a semi-submersible platform generally consists of a platform body, columns, a pontoon, and a number of support rods – a pontoon submerged under water, providing primary buoyancy, and columns connecting the deck body to the pontoon.

A semi-submersible obtains most of its buoyancy from ballasted, watertight pontoons located below the water surface and are away from wave action. Structural columns connect the pontoons and operating deck. The operating deck can be located high above the sea level owing to the good stability and therefore is kept well away from the waves.

With its hull structure submerged at a deep draft, the semi-submersible is less affected by wave loadings than a normal ship. However, with a small water plane area, however, the semi-submersible is sensitive to load changes and therefore must be carefully trimmed to maintain stability.

Semi-submersible platform can be used as both drilling and production platform. It has a series of advantages such as high safety factor, large deck space (up to 110 m/110 m in length and width), and strong expansion of the topside in the later stage. The deck area and load can be flexibly adjusted according to the actual situation. The platform is also flexible to move, the stability is relatively good, and the reliability is high. In addition, semi-submersible platform can be used for other offshore operation utilizations, including pipelayers, supply vessels, offshore lifting vessels, etc., especially widely used in deepwater oil and gas exploration.

History

The semi-submersible design was first developed for offshore drilling activities. Bruce Collipp (From “Wikipedia [n.d.](#)) of Shell is regarded as the inventor. But Edward Robert Armstrong (From “Wikipedia [n.d.](#)) may have paved the way with his idea of “seadrome” landing strips for airplanes in the late 1920s, since his idea involved the same use of columns on ballast tanks below the surface and anchored to the ocean floor by steel cables. When oil drilling moved into offshore waters, fixed platform rigs and submersible rigs were built, but were limited to shallow waters.

The first semi-submersible arrived by accident in 1961. Blue Water Drilling Company owned and operated the four column submersible drilling rig Blue Water Rig No.1 in the Gulf of Mexico for Shell Oil Company. As the pontoons were not sufficiently buoyant to support the weight of the rig and its consumables, it was towed between locations at a draft midway between the top of the pontoons and the underside of the deck. It was observed that the motions at this draft were very small, and Blue Water Drilling and Shell jointly decided that the rig could be operated in the floating mode. The first purpose-built drilling semi-submersible Ocean Driller was launched in 1963. Since the emergence of a semi-submersible offshore platform in the early 1960s, it has been widely used in the offshore oil exploration and development. In

Semi-submersible Platform, Fig. 2 Distribution of semi-submersible production platform (2008)

1975, the world's first semi-submersible production platform "DeepSea Pioneer" was built. Most of the semi-submersible production platforms were converted from drilling rigs in the initial stages of the development of floating production facilities. Due to the small number of drilling rigs available for modification since the 1990s, it became less attractive than FPSO. However, with the worldwide exploitation of deepwater and marginal oil fields, semi-submersible production platforms were once again favored by oil exploration companies after the 1990s. Its main operating blocks are mainly in the Brazilian waters, the Gulf of Mexico, the South China Sea, and the North Sea. Fig. 2 shows the semi-submersible production platform operational distribution in 2008 (2008 Semi Floating Production Vessel Poster n.d.).

Structural Features

The semi-submersible platform is composed of an upper deck, columns, a lower pontoon or rigs, and anchoring system. The advanced fifth-generation or sixth-generation semi-submersible drilling

platforms are all equipped with DP system. If DP system is not used, the platform is normally connected to the seafloor through the mooring system. Since its appearance, the structure of the semi-submersible platform has undergone many evolutions, and its appearance tends to be simple. Huge pontoon provides the buoyancy required for towing work.

The columns connect the pontoon and the upper deck. During operation, the pontoon and large proportion of columns are sunk into the water, which greatly reduces the water surface area and thus reduce heave motion amplitude of the platform. The larger water plane moment of inertia provides the stability required for the platform operation. In order to consider damage stability and cost-effect, the number of columns is generally 4 to 8.

The upper deck is the main place for equipment storage and personnel residency, providing work site and arranging production and living facilities. The money-maker of the platform, the rig, is installed on the deck. The accommodation facilities are always designed near helicopter platform, in case of emergency evacuation.

Semi-submersible Platform, Fig. 3 Offshore support vessel Toisa Perseus with, in the background, the fifth-generation deepwater drillship Discoverer Enterprise, over the Thunder Horse Oil Field. Both are equipped with DP systems

Dynamic positioning system (DP) is mostly installed on newly built semi-submersible drilling platform, because they are always expected to operate in deepwater area and DP operation can save great time and cost than those of traditional mooring positioning operation. DP system can be composed of 6–8 propellers installed beneath the pontoon, and their directions can be adjusted with 360 degree to counteract the wind load, current load, and second order wave load (Fig. 3).

Construction and Installation Process

The construction and installation process of the semi-submersible platform is very complex, time-consuming, and costly. At present, only a few big companies in the world can afford the construction and operation costs. Some of them can only undertake part of the construction work such as the construction of the hull. Nowadays, some international companies that are famous for their construction of semi-submersible drilling platforms are mainly located in East and Southeast Asia, for instance, Keppel Corporation and Sembcorp Marine Company in Singapore, Samsung Heavy Industries and Daewoo Shipbuilding and Marine Engineering Company in South Korea, and Raffles

Shipyard, Waigaoqiao Shipyard, and Dalian Shipyard in China (Fig. 4).

Vortex-Induced Motion Effect

For the conventional semi-submersible platform, the natural periods of roll, heave, and pitch motions are between 40 and 60s; when using the mooring positioning systems, the natural periods of surge, sway, and yaw motions are between one to several minutes, which are far from the general wave energy range that is normally between 5 and 30s. Therefore, the first-order wave motions including heave, roll, and pitch will be quite small and benefit the drilling operation very well. However, under the action of the second-order low-frequency wave force effect, semi-submersible platform can have obvious slow-drift motion on surge and sway, which has to be borne by mooring system or DP system. In addition wave run-up phenomenon is another important phenomenon often being concerned, especially under severe sea state (Danmeier et al. 2008). Recently, with the application of deep-draft semi-submersible concept, vortex-induced motion (VIM) problem has also arisen to cause much attention.

Semi-submersible Platform,

Fig. 4 Construction and installation process of semi-submersible platform in different shipyards

Vortex-induced motion (VIM) is one of the hydrodynamic problems for deep-draft semi-submersible platform with large column height. Traditional semi-submersible platforms have relatively low drafts, and the height of the underwater part of the column is small, so its vortex-induced motion is not obvious. However, with the development of petroleum exploration toward the deep sea in recent years, the loading requirements for semi-submersible platforms have been continuously improved, and the draft design draft has also gradually increased, that is, it has developed into a deep-draft semi-submersible platform.

The semi-submersible platform is a typical multi-column floating body. The tail of the

column will generate periodic vortex shedding under certain flow conditions. The vortex shedding will generate pulsating pressure. Under certain flow conditions, the vortex will follow the surface of the cylinder and generate alternating falling motion, which leads to the horizontal resonant vibrations that cause vortex-induced motion (VIM). When the natural frequency of the platform system is close to the frequency of vortex shedding, this resonant motion is even more serious, resulting in a large low-frequency cycle (LFC) fatigue damage to the mooring and riser systems. Compared with the high-frequency damage caused by waves, the dynamic tension amplitude caused by the

vortex-induced kinematics is much greater, resulting in more severe fatigue problems. In addition, a larger vortex-induced response will also have a greater impact on the platform's mooring and positioning capabilities. Therefore, in the design stage of mooring and riser systems, accurately predicting the vortex-induced motion characteristics of the platform under the action of the ocean current provides an important reference for checking whether the fatigue lives of mooring and riser systems satisfy the requirements for the whole service life.

The characters of VIM of semi-submersible platform are different with those of other offshore structures, such as SPAR platform. Semi-submersible platforms usually consist of a pontoon, cross braces, and multiple columns, so under the vortex-shedding excitation effect, the vortex-induced motion characteristics of the semi-submersible platform are quite different from that of a standpipe or a slender body. For a deep-draft semi-submersible platform, the maximum vortex amplitude A/D can reach 0.5–0.6 (where A is the amplitude of transverse vortex-induced motion, and D is the dimension of platform for dimensionless), which will affect the fatigue life of anchor chain and the hanging catenary riser. The vortex-induced motion is related to the maximum displacement of the platform, which will increase the drag force acting on the platform, especially when the vortex-induced motion is severe, and even affect normal drilling operations. Therefore, the VIM has become a challenge that restricts the development of the deep-draft semi-submersible platform.

In addition, VIM of semi-submersible platform is special due to the multi-number of columns. Compared with single column platforms, such as the spar platform, the vortex shedding of each column of semi-submersible is superimposed on each other, and the effect of interference makes the VIM characteristics of the deep-draft semi-submersible platform more complicated. Because the importance of predicting VIM effect during the design stage of deep-draft semi-submerged platform, many studies have been conducted based on theoretical analysis and basin experiment methods.

Wave Slamming

With the development of global ocean exploration and development, the semi-submersible platform has become one of the main tools for the development of offshore oil and gas by its advantages. The basic structural design and analysis have become the important technical content in the basic design. DNVGL (DNV RP-C103 Column-stabilized units 2005) classification requirements for the basic structural design of semi-submersible offshore platforms include completion of overall strength analysis, local strength analysis, web frame strength analysis, air gap analysis, wave slamming (on lower deck by wave loading) strength analysis, etc. The strength analysis of the lower deck structure when attacked by the wave slamming load is an important part in the basic structural design report. In severe sea state, the wave will impact the lower deck structure, which may lead to serious structural damage. Therefore, it is necessary to consider the effect of wave slamming load on the lower deck during the design process.

Classification societies provide some analysis procedure for the wave slamming effect check.

Rule-Based Check Method

Rule-based check method is the most easily used method by designers, because they only need to conform to the rules of classification societies and can maintain a high working efficiency. For instance, the DNVGL states that the wave load calculation formula calculates the average slamming pressure (DNV RP-C205-environmental conditions and environmental loads 2007):

$$P_s = 0.5\rho \cdot C_{pa} \cdot v^2$$

In the formula,

P_s – the average attack pressure.

ρ – the liquid mass density, the calculated value of 1025 kg/m³.

C_{pa} – the load coefficient; $C_{pa} = 2\pi$ when the flat bottom surface is impacted; $C_{pa} = 5.15$ when the smooth cylinder is subjected to impact.

v – the relative normal velocity between the water surface and the lower deck surface.

According to this formula, for all areas in the lower deck of the semi-submersible probably subjected to wave load impact calculated in the air gap analysis, the relative speed and slamming force at the impact of the wave slamming load on these areas in all wave directions are calculated.

With the wave slamming load calculation results, the bottom of deck structure of semi-submersible can be checked by classification societies' rules. There are many rules for structural strength check. So, this is a convenient working procedure. Nevertheless, the accuracy of this method relies much on the classification societies' rules, so it is classification societies' duty to guarantee the feasibility and accuracy of those rules.

Numerical Simulation Method

Numerical simulation is one of the most important methods to analyze and assess the structural safety of the lower deck structure of semi-submersible platform. There are many commercial codes available being used to do the numerical simulations of wave slamming, including ABAQUS, FLUENT, and LS_DYNA. One of the advantages of numerical simulation method is the relative accuracy that this method can provide, and the slamming process can be shown in much detail in time series. The other advantages of the numerical simulation method is that the simulation results can find some critical weakness points of deck structure, which will help to strengthen the deck structure accurately. Nevertheless, there are also some weak points of this method, one of the most critical one is the high cost of human labor and computation time. For example, it may be a challenge task for a designer to learn and use sophisticated CFD codes such as FLUENT. Furthermore, the simulation results could be versatile for different users (Qinjing et al. 2011).

It is believable that with the improvement of IT technology, numerical simulation method will become more and more popular and reliable. At that time, the calculation of many nonlinear phenomena will employ numerical simulation methods during the design phase.

Air Gap

Air gap has much relationship with wave slamming effect in previous section. For semi-submersible platforms, the vertical support structure below these platforms, namely, columns, are generally more slender, which is to withstand the wave load, thereby enhancing its ability to work in harsh sea conditions. If the initial air gap of the platform is small, the waves can easily slam the structure of the lower deck and platform directly, which can result in large slamming wave load and cause serious structural damage and endanger the people onboard and even, sometimes, overturning of the platform. So for the platform, air gap must not be too small, so as to avoid damage to the platform.

During the design stage of offshore platform, especially semi-submersible platform, air gap is always one of the most critical issues. It is a highly nonlinear problem and plays a very important role in the two major factors – the response of wave height and the platform vertical motion amplitude.

When considering the wave height calculation, it normally applies both linear and nonlinear wave theories. If only linear wave theory is used, it will be inevitably underestimating the wave climbing value, which is more serious with the increase of wave steepness. Comparatively, the forecast values by applying both linear and nonlinear wave theories are in better agreement with the experimental values. The other calculation issue is the motion amplitude of the platform. If only fixed platform is considered, the air gap problem can be much simplified, but if the motions of floating offshore platform are considered, the forecast of air gap value will become more complicated, because the phases of both motions and that of wave height need to be both considered.

In general, the nonlinear issue of air gap forecast is more accurate than that of the linear forecast value, which is worth exploring and practicing.

Air Gap Forecast of the Semi-Submersible Platform

For semi-submersible platform, it has two types of deck superstructures – open deck structure

Semi-submersible Platform, Fig. 5 Wave slamming on semi-submersible platform

and closed deck structure – which refer to whether the deck superstructure of the platform is open design or closed design. In the case of an open design, small waves on the deck or lashing can damage the safety of lives and property facilities on the platform and so it compulsorily required that the air gap of the platform must be kept positive. As for the closed superstructure design, due to the better protection brought by the enclosed superstructure, slight waves slamming will not have a significant impact on the platform deck, so it can be applied to the harsh marine environment.

Taking into account the cost of the platform construction, the large distance between the bottom of deck structure and the still water surface, namely, the great design value of the initial air gap, often means increasing construction cost. Therefore, for most latest version semi-submersible platforms, in order to avoid the negative air gap completely, it is more economical to perform local strengthening check than to increase the initial air gap (Sweetman et al.) (Sweetman et al. 2002a). Thus, semi-submersible can withstand some wave slamming without the need to increase initial air gap (Fig. 5).

For floating platforms, such as semi-submersible platforms, the interference between platforms motion and wave is serious. Due to the effects of wave diffraction and scattering, the crests of some parts of the platform are often overlapped with each other so that the response of the air gap can be amplified or reduced. Therefore, the forecast of air gap is a high nonlinear problem, and it is quite complicated. At present, CFD and numerical calculation are the most reliable methods for the air gap forecast.

Development of Air Gap Forecast Methods

At present, numerical prediction of the air gap mainly includes CFD forecast method and numerical calculation forecast method based on potential flow theory. In addition, basin experiment is also used for air gap prediction.

For CFD method, it can provide accurate forecasting results with good visual effect, if the required technologies can be used in a correct way. There are many successful examples in air gap forecasting by some famous CFD tools, for instance, OpenForm, Fluent et al. But CFD method also has its drawbacks, such as high time-consuming and labor-consumption, and insufficient reliability et al.

Compared with CFD method, numerical calculation forecast method based on potential flow theory costs much less and easily to be mastered, so it is normally used for engineering application. Many popular commercial tools, for instance, WAMIT, SESAM, MOSES, and AQUA, can be used to do the air gap forecast calculation. Nevertheless, it is also needed to point out that sometimes numerical calculation method can underestimate the relative wave height, and thus may not provide a conservative prediction result (Fig. 6).

There are some findings from air gap forecast research. It is found that linear numerical methods often underestimate the extremes of relative wave front rise, so basin model testing is essential for designing a new platform. Sweetman (Sweetman et al. 2002b) believes that it is more economical to allow proper negative air gap phenomena in the extreme sea conditions and to reinforce the local structure, compared to always be without wave slamming. Simos and Fajarra (Simos et al. 2006)

Semi-submersible Platform, Fig. 6 Wave slamming simulation for semi-submersible through CFD technology

from the University of São Paulo concluded that the plateau is affected by waves, and the air gap response of the platform will have significant nonlinear characteristics (especially the response wave height around the platform column) when the incident wave's steepness exceeds 4%. In 2009, Lwanowski et al. used ComFLOW software to conduct a theoretical study of the platform (Bogdan et al. 2009). The software predicts the air gap performance of the platform by capturing the N-S equation combined with the improved VOF method and captures the wave climbing and wave-ups around the platform. The results show that this method can simulate the wave scattering and wave surface distribution around the column accurately. Stansberg et al. used the potential flow software WAMIT to simulate the wave height and air gap around the semi-submersible platform (Stansberg 2007). It was found that the nonlinear method can basically meet the requirements of engineering forecast under some special conditions. However, when the wave steepness is large, there is a big deviation from the test value.

In addition, besides replying on calculation method, basin experiment is another alternative way, and it can give relatively more accurate and direct forecasting air gap data. However, similar to the disadvantage of CFD method, basin experiment has the shortcoming of high cost and human labor, which may not be affordable by most scholars.

Semisubmersible Vehicle (SSV)

► Semisubmersible Vehicle Autopilot Control System

Semisubmersible Vehicle Autopilot Control System

Changhui Song
School of Engineering, Westlake University,
Hangzhou, China

Synonyms

Autopilot control system; Semisubmersible vehicle (SSV); Unmanned surface vehicle (USV); Unmanned underwater vehicle (UUV)

Definition

The **semisubmersible vehicle** is a fuel-powered underwater vehicle that most of its structure is below the water surface and its snorkel extends above the water surface. The radio antenna is fixed on the snorkel for real-time data transmission and remote control. Different from traditional unmanned surface vehicles (USVs), the semisubmersible vehicle can use the differential global positioning system (DGPS) mounted on snorkel duct for precise positioning, which has greatly enhanced the opportunity for the use of the semisubmersible vehicle. As the snorkel is the only part of the semisubmersible vehicle to be affected

by sea state, it is much more stable in waves than surface drones or small vessels. The task of the semisubmersible vehicle autopilot control system is to achieve automatic attitude and depth control.

Scientific Fundamentals

The autopilot control system of semisubmersible vehicles faces three major challenges: some hydrodynamic coefficients unknown, disturbances from unpredicted sea environments, and the coupling states' effects. The dynamical performances of the vertical plane control are sensitive to the sharply changing of these coupling states and complex disturbances. Due to the highly nonlinear marine vehicles and the significant environment disturbances, it is a great challenge to control unmanned semisubmersible vehicles (USVs) without knowing the model parameters.

Sensor, Control and Communication, and Power System

As mentioned in the background above, one of the advantages of this semisubmersible is the capability to maintain the communication link to support vessel or shore station and location updated by GPS transceiver. As a categorized unmanned surface vehicle, the topmast of the surface section must have enough space to put some environmental sensors such as temperature, barometric pressure, speed, and wind direction or popular known as weather sensor station. With the most body submerged, it has enough space to put the most common underwater survey equipment such as obstacle avoidance sonar, side-scan sonar, and dual-frequency echo sounder. Figure 1 shows the control architecture of semisubmersible vehicle.

For communication, two types of systems will be provided on this vehicle. As a fact that almost the unmanned and autonomous capability surface vehicles have the mission to deploy on the remote area and very far from support vessel or shore station, the best communication must be based on the satellite system. The other widely used communication method is radio communication.

Semisubmersible Vehicle Autopilot Control System, Fig. 1 Control architecture of semisubmersible vehicle (Kartidjo et al. 2015)

To accommodate the long-endurance capability and operation of many sensors, this vehicle is equipped with a high density of battery as the power source. The main criteria of battery beside the capacity are the longest cycle it has (Kartidjo et al. 2015).

6-DOF Equation of Motion of the Vehicle

We formulate the motion of the semisubmersible vehicle using a 6-DOF rigid body model. To

describe rigid body motion, two coordinate systems need to be defined: the global coordinate system and the body-fixed frame. Figure 2 shows the coordinate systems used for vehicle modeling. Based on Newton's second law, Kirchhoff's equation of motion in the body-fixed frame of the towing vehicle and the towfish can be written as shown in Eq. (1).

$$\begin{aligned}
 m_m [\dot{u} - vr + wq - x_{Gm}(q^2 + r^2) + y_{Gm}(pq - \dot{r}) + z_{Gm}(pr - \dot{q})] &= X_{hyd} + X_{prop} + X_{int} \\
 m_m [\dot{v} - wp + ur - y_{Gm}(q^2 + r^2) + z_{Gm}(qr - \dot{p}) + x_{Gm}(pq - \dot{r})] &= Y_{hyd} + Y_{prop} + Y_{int} \\
 m_m [\dot{w} - uq + vp - z_{Gm}(q^2 + r^2) + x_{Gm}(pq - \dot{r}) + y_{Gm}(pr - \dot{q})] &= Z_{hyd} + Z_{prop} + Z_{int} \\
 I_{xm}\dot{p} + (I_{zm} - I_{ym})qr + m_m[y_{Gm}(\dot{w} - uq + vp) - z_{Gm}(\dot{v} - wp + ur)] &= K_{hyd} + K_{prop} + K_{int} \\
 I_{ym}\dot{q} + (I_{xm} - I_{zm})pr + m_m[z_{Gm}(\dot{u} - vr + wq) - x_{Gm}(\dot{w} - uq + vp)] &= M_{hyd} + M_{prop} + M_{int} \\
 I_{zm}\dot{r} + (I_{ym} - I_{xm})pq + m_m[x_{Gm}(\dot{v} - wp + ur) - z_{Gm}(\dot{u} - vr + wq)] &= N_{hyd} + N_{prop} + N_{int}
 \end{aligned} \tag{1}$$

Semisubmersible Vehicle Autopilot Control System, Fig. 2 Coordinate systems of semisubmersible vehicle (Park and Kim 2015)

Eq. (1) is the equation of motion of the semisubmersible vehicle, where $[u, v, w]^T$ is the surge, sway, and heave directional linear velocity in body-fixed frame, and $[p, q, r]^T$ is roll, pitch, and yaw angular velocity in body-fixed frame. $[x_{Gm}, y_{Gm}, z_{Gm}]$ is the position of the center of gravity of the semisubmersible vehicle. The subscript *int* refers to the interaction force, the subscript *hyd* refers to the hydrodynamic force, and the subscript *prop* refers to the propulsion force. As mentioned earlier, the equation of motion of vehicles is described in the fixed-body frame (Park and Kim 2015).

In the actual control system, we pay more attention to the vertical control of semisubmersible vehicles. So the dynamic model can be simplified properly. The vertical plane states of the semisubmersible, such as the depth, pitch angle velocity, and pitch angles, are usually coupled with surge speeds. And these states are often corrupted by the unexpected surge or the sea wind. Moreover, pitch angles and submerged depths should be confined according to the mechanisms of the studied semisubmersible vehicles system.

PID Controller

As the starting point and to provide a baseline for comparison of designs, a PID control law was employed. In the digital domain, this control law has the form:

$$\delta_z(k) = k_P e_z(k) + k_I \sum_{l=1}^k e_z(l) + k_D \frac{e_z(k) - e_z(k-1)}{T}$$

$$e_z(k) = z(k) - z_d \quad (2)$$

Zhou et al. (2019) set the sampling period to $t = 0.2$ S and set the submergence depth of the vehicle to 1 m in the control system. The control parameters used in the control system are:

$$k_P = 3, k_I = 0.5, k_D = p$$

Although the response of the PID controller is stable, the transient and steady-state response is somewhat poor. Moreover, the pitch angle is not well controlled, appears as the semisubmersible vehicle is running through the sea, which indicates that the depth of the vehicle is susceptible to the disturbance from the sea environment.

Fuzzy Dynamic Feedback Controller

The fuzzy dynamic feedback control algorithm can guarantee robustness against external parameter unknown and poor sea environment. Due to the limited submersible depth, motions of the semisubmersible vehicle are directly influenced by wave forces coming from water surfaces. Therefore, the external disturbances on the semisubmersible vehicle are difficult to be described by mathematical expressions. Moreover, the model parameters of the semisubmersible vehicle are unknown, which makes the controller more difficult. Control parameters of the fuzzy rule-based state-feedback controller are auto-adjusted by fuzzified states errors and surge speeds. Figure 3 depicts the block diagram of the depth control of the semisubmersible vehicle.

State Feedback Controller

One alternative to PID control is to assume that the system can be adequately represented by linear time-invariant dynamics for a specified surge speed and design a state feedback law for the vehicle. Simplify the system model and describe its state-space model as:

Semisubmersible Vehicle Autopilot Control System, Fig. 3 Fuzzy controller of the semisubmersible vehicle (Zhou et al. 2019)

$$\begin{aligned} \begin{bmatrix} \dot{e}_z \\ \dot{e}_\theta \\ \dot{e}_q \end{bmatrix} &= Ax + B\delta_s \\ &= \begin{bmatrix} 0 & -u & 0 \\ 0 & 0 & 1 \\ 0 & a_1 & a_2u \end{bmatrix} \begin{bmatrix} e_z \\ e_\theta \\ e_q \end{bmatrix} \\ &\quad + \begin{bmatrix} 0 \\ 0 \\ bu^2 \end{bmatrix} \delta_s \end{aligned} \quad (3)$$

The key idea of the feedback control is to assign the eigenvalues predesigned according to the desired performances of the system. The eigenvalues are equal to the roots of the character equation of the considered system if there is no pole-zero cancellation. The poles of the closed-loop system can be located at any place according to the desired control performances if the plant system is fully controllable (Gruyitch 2013). If a state feedback control law is designed for a given surge velocity, the pole assignment problem has a solution if and only if (3) is controllable. Preset the form of the feedback control law as:

$$\begin{aligned} \delta_s &= k_{e_z}e_z + k_{e_\theta}e_\theta + k_{e_q}e_q \\ &= [k_{e_\theta} \ k_{e_\theta} \ k_{e_q}] \begin{bmatrix} e_z \\ e_\theta \\ e_q \end{bmatrix} = K \begin{bmatrix} e_z \\ e_\theta \\ e_q \end{bmatrix} \end{aligned} \quad (4)$$

where k_{e_z} , k_{e_θ} , and k_{e_q} are feedback control parameters. Suppose also that it is decided to place the controlled system poles at λ_{e_z} , λ_{e_θ} , and λ_{e_q} in the open left-half of the complex plane.

$$\det(sI - (A - BK)) = (s - \lambda_{e_z})(s - \lambda_{e_\theta}) \times (s - \lambda_{e_q})$$

With further analysis, the control parameters can be determined as:

$$\begin{cases} k_{e_z} = \lambda_{e_z}\lambda_{e_\theta}\lambda_{e_q}\tilde{b} \\ k_{e_\theta} = -(\lambda_{e_\theta}\lambda_{e_q} + \lambda_{e_z}\lambda_{e_\theta} + \lambda_{e_z}\lambda_{e_q})\tilde{b} \\ k_{e_q} = (\lambda_{e_z} + \lambda_{e_\theta} + \lambda_{e_q})\tilde{b} \end{cases}$$

where $\tilde{b}$ is decided by the known parameter M_σ (Zhou et al. 2019).

Sliding Mode Controller

The control parameters cannot be provided for the model-based control algorithm, which leads to the

Semisubmersible Vehicle Autopilot Control System, Fig. 4 Dorado vehicle (ISE Ltd. 2017)

undesirable control performances of the system since the depth motion model parameters regarding the unmanned semisubmersible vehicles are unknown. For this purpose, a multi-identification model-based dynamic sliding mode control algorithm is presented for the investigation of system's control problem on the desired depth. In the proposed algorithm, the average-fitting-error method is used to reduce the excessive redundant model parameters, and thus the optimum model parameters are provided for the control algorithm by switching methods. And the state feedback method is used to bring about the chattering exponential decay of sliding mode controller so as to reduce the settling time. The experimental results of lake trials demonstrate that the proposed algorithm could offer the best model parameters for sliding mode control, and the dynamic sliding mode control with multi-identification models is capable of ensuring BQ-01 vehicle to achieve the ideal control performance (Zhou et al. 2017).

Key Applications

Semisubmersible vehicles were first used for military purposes, mainly in anti-mine operations. Only a few countries have mastered the relevant technology and developed equipment, including Canada, France, the United Kingdom, the United

States, and China. In recent years, with the increasing demand for marine surveys, semisubmersible vehicles may expand into the civilian field, for example, ocean seismic survey work.

Dorado Vehicle

The growing threat from new-generation mines that are increasingly more difficult to detect has stimulated the demand for new mine-hunting systems that offer improved safety and operational efficiency. The Dorado vehicle, shown in Fig. 4, in operational service with the Canadian Department of National Defence, was developed to meet this need, which can be considered one of the first examples of truly autonomous USVs (Young et al. 2006). The Dorado vehicle is capable of towing a sonar towfish at speeds up to 12 knots and depths to 200 m. The towfish was developed to follow the seabed at low altitudes and is fitted with a multi-beam side-scan sonar.

SeaKeeper Vehicle

Based on the experience in the design and production of several generations of MCM vessels, the French company DCN had developed the SeaKeeper, shown in Fig. 5, as an answer to face the challenging threat of modern mines. SeaKeeper was presented for the first time in Brest in June 2003 in the complete configuration including the “dry segment.” SeaKeeper was the

**Semisubmersible Vehicle
Autopilot Control
System, Fig. 5** SeaKeeper
vehicle (ISE Ltd. [2018](#))

Semisubmersible Vehicle Autopilot Control System, Fig. 6 AN/WLD-1 vehicle (Luca [2017](#))

latest solution available for sonar reconnaissance against the most modern mines at that time. With a vehicle remotely controlled by radio, it offered the highest level of safety for the crew, together with unmatched performance in terms of area coverage rate. The system, integrated by DCN company, had raised interest in several navies in the world. During 13 days of trials and demonstrations, the

SeaKeeper achieves more than 100 h of sonar operation, showing remarkable reliability for the prototype (Waquet [2003](#)).

AN/WLD-1 Vehicle

Lockheed Martin's AN/WLD-1 RMS, shown in Fig. 6, is a key component of the Littoral Combat Ship's mine countermeasures package (Button

et al. 2009). The system consists of a 7-m semi-submersible autonomous remote multi-mission vehicle (RMMV) which tows the AQS-20A Variable Depth sensor. The RMS has sometimes been referred to as a “snorkeler class” unmanned surface vessel due to the snorkel required above the surface for the system’s diesel engine operation. The RMMV can be preprogrammed to perform autonomously or be manually controlled via line of site or over-the-horizon data link. The Navy successfully concluded the second and final phase of reliability testing of the littoral combat ship (LCS) remote minehunting system (RMS) off the coast of Palm Beach, Florida, enabling the service to progress toward developmental testing, in June 2013. The system completed more than 850 h of testing during 47 missions over a 4-month period.

SASS Vehicle

The Survey Autonomous Semi-Submersible (SASS) vehicle, shown in Fig. 7, for Ocean survey was developed by UK company ASV Ltd. (Bertram 2008). The platform which is intended to enhance or even replace conventional survey vessels will provide cost-effective deployment of ocean sensors. SASS involves an unmanned submerged torpedo-like body running below waves with a strong upright strut penetrating the water

surface. The strut provides buoyancy, air for propulsion, and radiofrequency coverage for communications and positioning. The 6-m vehicle has a maximum speed of 10 knots and a payload capacity of up to 200 kg. It is designed to be launched and recovered from a ship or deployed from the shore. The vehicle permits a wide range of sensor operations for near-surface and deepwater applications. To date, the vehicle has been successfully operated with sonar’s for the underwater survey and with cameras for above water surveillance. Furthermore, the vehicle has been a leading candidate for towed side-scan sonar operations such as deepwater naval mine warfare, and the vehicle has been evaluated by the UK’s Ministry of Defence under their concept capability demonstrator program.

USS Vehicle

USS vehicle, a predecessor to the Remote Minehunting System, was a diesel-powered air-breathing vehicle with a tall narrow mast and the majority of its structure below the water surface (Alleman et al. 2009). The USS vehicle, shown in Fig. 8 (left), is an autonomous semisubmersible vehicle that could be used for shallow-water hydrographic surveys and surface surveillance. This diesel-powered vehicle has an operational speed of

**Semisubmersible Vehicle

vehicle (Bertram 2008)

Semisubmersible Vehicle Autopilot Control System, Fig. 8 USS 6300 vehicle and conceptual model of USS 9500 (Alleman et al. 2009)

Semisubmersible Vehicle Autopilot Control System, Fig. 9 BQ-01 vehicle (Zhou et al. 2019)

8 knots with an associated endurance of 48 h in sea state 4. At a survey speed of 4 knots, the vehicle has an impressive endurance of nearly 100 h. The vehicle has a payload capacity of 300 kg for sonars, computers, sensors, winches, and camera equipment. A recently constructed vehicle, the USS 6300 for C&C Technologies in the United States, is fitted with a Klein 5000 side-scan sonar and Simrad EM3002 multibeam sonar for commercial hydrographic survey. USS 9500 will be designed to offer long-range (1500 miles) survey and

surveillance operations within the “Exclusive Economic Zone” (EEZ); this 9.5-m diesel-powered vehicle has been designed to a rugged specification, with the ability to operate in sea state 5/6 at moderate speeds, with a sprint speed of 20 knots and the ability to remain at sea for extended periods of up to 30 days.

BQ-1 Vehicle

BQ-01 system, shown in Fig. 9, is a semisubmersible vehicle that should not completely submerge

into water, or else some water may flow into it from its chimney and breaks down some important parts equipped inner system. To make sure the USV safety, the pitch angles, and the submerged depth are confined to $[-15, 15]$ degrees and $[0, 3]$ m, respectively. The features of BQ-01 are as the followings: its power source is a diesel engine, its body can submerge a certain depth, its breather pipe should not be awash, otherwise some water will enter its control cabinet. The length of BQ-01 is 5.9 m, and the width is 2 m. Its performance basic indices are the maximum surge speed 15 knots, the maximum submerged depth is 3.5 m, and the strongest drag force is 10,000 N@10kn (Zhou et al. 2017, 2019).

Service Ships

Jie Cui, Cheng Chen, Cong Gao, Xin Chen, Dong-Qing Miao and Wei Xu
College of Naval Architecture and Ocean Engineering, Jiangsu University of Science and Technology, Zhenjiang, China

Definition

Service ships are vessels designed to provide support for commercial ships and industrial vessels; some of them are also used for professional work.

Scientific Fundamentals

Composition and Basic Type

There are many types of work ships depending on the function, such as tugs, icebreakers, fire boats, etc.

A tugboat is a type of vessel that maneuvers other vessels or floating structures. The vessel itself does not have the ability of loading and unloading. And it is mainly used to tow barges loaded with cargo and other different kinds of engineering ships. Towing facilities include towing hook,

Service Ships, Fig. 1 Inland river tug (<http://www.quanjing.com/>)

Service Ships, Fig. 2 The icebreaker "Bolheim"

towing column, mooring winch, etc., and at the same time, the aft deck has a large working area for operating easily (Wu 2017) (Fig. 1).

Icebreakers are special vessels designed to open waterways in ice waters and to rescue trapped vessels. As early as 1857, Sweden built the world's first real icebreaker "Bolheim". The hull structure of an icebreaker is quite different from that of a general ship. The ship type, bow, propulsion, and propeller are the main distinguishing areas.

Icebreakers generally use two methods (continuous icebreaking and collisional icebreaking) for icebreaking operations. In addition to the use of

their own weight, traditional icebreakers often need to use the cooperation between the front and rear pressure tanks to complete the icebreaking work (Fig. 2).

Fireboats are professional ships for firefighting and extinguishing in ships or buildings near the shore. Fireboats look like tugboats, so there are also fire boats that double as tugboats. The ship is equipped with high-power water pump system, high-pressure spray gun, and fire-extinguishing agent, as well as rescue workers and medical equipment. Fire hoses are located on fire towers high above the water or on the top of a thickened mast with a range of more than 40 m. The ship

Service Ships, Fig. 3 Fire of ocean-going freighter (<http://www.sina.com.cn/>)

also has a water curtain in order to get deeper into the fire area. When entering the fire area, the whole ship will be covered by a water curtain. Fireboats have a high speed and good seakeeping and require good maneuverability, so they can perform firefighting missions in narrow waterways or crowded ports (Fig. 3).

Development History

In the seventeenth century, ships began to use steam engines. The first truly tugboat was the *Charlotte Dundas*, which was powered by a steam engine and paddle wheels, mainly along the coast of Forth and Clyde near Glasgow. In order to improve the efficiency of propulsion, the propellers began to appear on tugboats in the mid-nineteenth century, and the size and towing capacity of the tugboats also increased significantly. The surge in demand for tugs in the first and second world wars drove the development of tugs, and the pace of tugboat modernization was accelerated by the development and applications of diesel engines, propulsion technologies, navigation technology, etc. Today, tugboats still play an important role in port operations, inland water transport, and marine development (Chen 2010).

Since 1900, Russia has been the first to build icebreakers on a large scale. Most of these icebreakers are used for overseas sailing. Among the early construction of icebreakers, the first vessel to sail in the Arctic was the “*Yelmaf*”. In 1957, the world’s first icebreaker driven by nuclear power was successfully built. It was the “*Lenin*” built by the former Soviet Union. Nuclear power technology is a major breakthrough in the field of icebreaking.

In 1969, the construction process of modern icebreakers was rapidly developed. The USA used these new technologies to transform the transport ship “*Manhattan*” into a 115,000 t commercial icebreaker. Since then, a large number of high-quality icebreakers have emerged. In 1980, Canada built a new type of icebreaker, the “*Kigoglik*”, it mainly uses a spoon-shaped head similar to a reamer, which can greatly reduce the friction between the broken ice crystal and the hull, thus effectively improving the ship’s swing performance. In the 1980s, scientists invented a “bubble drag reduction system” that would prevent the icebreaker from being caught by the ice when it was icebreaking, allowing the ship to continue in the ice.

In 1762, the first fireboat appeared in Paris. At that time, it was mainly to deal with the fires that occurred on the wooden bridge over the Seine and the fires that occurred on the boats. By 1764, there were a total of eight fireboats in Paris which were equipped with handcuff pumps. They did not quit service until the nineteenth century. The rise of the industrial revolution in the nineteenth century brought the busyness of American ports, which increased the risk of fire, making Boston introduce lifeboats for firefighting. In 1888, the Paris Fire Brigade Commander asked the municipality for a steam fireboat, but his request was not met. Until 1931, due to the soaring fuel prices, in order to reduce costs, fireboats began to use diesel drives instead of steam drives (Shi 1990).

Key Technology

The tugboat is characterized by its small hull, high power, high tractive force, solid structure, strong fenders, and anti-collision equipment, which make the vessels have good stability and maneuverability. Meanwhile, excellent barking performance is very necessary for the tugboat. During towing operation, the tugboat will have a large heeling because of transverse urgent traction from towing cable. Therefore, in order to ensure the transverse stability, the beam will be relatively large and the length-breadth ratio will be smaller

than that of the ordinary transport ship (Yang et al. 2010).

In order to keep the good speediness and reliability of tugboats, double engine-paddle propulsion system is basically applied in modern towboats and sometimes especially for four engine-paddle propulsion system. Meanwhile, adjustable pitch paddles have been utilized in most of boats. For keeping excellent maneuverability, lateral thruster and sometimes full-swing devices will be installed in bow and stern of most towboats, respectively (Fig. 4).

Icebreakers generally use two methods: continuous icebreaking and collision icebreaking. In addition to using their own weight, traditional icebreakers generally need to use the cooperation between the front and back water tanks. For example, when heading to break the ice, the back water tank will be filled with water, so that the ship will be upward-headed, so that the front part of the ship will be pressed on the ice, and then the forward water tank will be filled with water, and the back water tank will be drained, so as the ship's center of gravity moves forward, the purpose of crushing the ice will be achieved. When breaking the ice from left to right, the ballast tanks of the ship will be flooded alternately from left to right, which will make the ship shake from left to right, thus breaking the ice (Bostrom 2018) (Fig. 5).

Service Ships, Fig. 4 Operations of tug (<http://www.quanjing.com/>)

Service Ships, Fig. 5 The icebreaker (<http://www.baidu.com>)

When the thickness of ice does not reach the designed thickness of icebreaker, the continuous icebreaking method is adopted. Propelled by propellers, icebreakers, which slowly and undulately break through the ice, can sail about 9.2 km/h through the ice. If the ice is thicker than the maximum ice break the icebreaker is designed to be, or if it is in more complex ice accumulation, thick ice zones, and more severe ice ridges, then the impact icebreaking method is used. First, the icebreaker needs to move back a distance of one or two captains and then speed up the collision. The tilting bow of the icebreaker can easily run onto the ice surface, in the thick ice area or encountered ice ridge, through repeated impact of the method of breaking the ice (Wei et al. 2017).

The advanced external fire protection system is the core part of the firefighting vessels. External fire protection system consists of external fire-extinguishing system, external foam fire-extinguishing system, self-spraying water curtain protection system, hydraulic lifting device, and external fire monitoring system. The advanced system design can transfer the ship from the navigational state to the fire state in the shortest time. The arrangement of the external firefighting system should have a certain height from the surface of the water due to the consideration of the scope

of action, and it should be arranged more in the top area of the firefighting vessels, so it is often arranged in the top area of the fireboat. Taking account of the personal safety of the firefighters, remote control of the cab should be used as much as possible, unless manual operation is necessary (Fig. 6).

Main deck and left and right sides of the upper deck of firefighting vessels shall be provided with fixed water-spray system devices, protecting the hull, superstructure, and deckhouses with water-spray, including the vertical surface of the base and parts of the fire monitor. Water curtain protection can absorb part of the convection and radiation heat, which can protect firefighters from being burned by large fires. Moreover, it can also prevent glass windows from being cracked by fire. At the same time, fireboat shells can be cooled (Shi 2011).

The hull and superstructure of firefighting ships and the peripheral walls of deckhouses must be steel. Doors and window frames on all peripheral walls must also be steel (aluminum). Firefighting vessel's glass windows (especially the big glass window in the cab) should be equipped with tempered glass that is resistant to air blasts to avoid accidental casualties of crew members and firefighters.

Service Ships, Fig. 6 Firefighting vessels (<http://www.pic.sogou.com/>)

Key Applications

With the advancement of technology and changes in people's needs, service ships are constantly evolving, and the overall trend is modernization, specialization, and multifunctionality.

Along with the drafting object increasing and improved requirement for drafting efficiency, the function for tugboat has been enhanced continuously. More advanced equipment has been utilized, and the tugboats have already entered the scope of high value-added ships. The number of newly built tugboat has already reached an unprecedented level, and the development of tugboats has directed to a functional and intelligent orientation (Tang et al. 2016).

The main shipyards for tugboats manufacturing are mainly located in European and American nations and China. The total number of tugboats under construction is currently around 400, and it is the USA which possesses most of the tugboats. There are several decades of history for tugboats manufacturing in our country, and enriching experience has been gathered. The design and manufacturing technology for tugboats has achieved great progress and reached the international advanced level mainly including harbor

tugs, offshore and inshore towboats, and multi-purpose stand by ship serving offshore oil platform (Fu 2010).

Versatility

Due to the restrictive factors in economics, there are drafting functions as well as fire control, marine salvage, supply, and diving work functions in towboats which present the multifunctionality trend.

For instance, the “De Hong” tugboat which was designed by Shanghai Merchant Ship Design and Research Institute in China is mainly used in marine salvage including marine long-distance drafting for salvage boats, wrecked offshore drilling platform, stranded reef ships, and boats lacking of maneuverability. Meanwhile, there are also plugging, drainage, and firefighting ability to wrecked ships, setting sail and anchoring ability for marine platform, drafting ability for buoy and undulant wrecked boat, boat hauling and transportation, and marine residuum collection functions. Moreover, bigger cabin has been arranged during preliminary design phase to load the deck cargo and lance pipe so that this ship can also be used as supply boat.

Intelligentization

Along with the increasing tasks for towboats and burden reducing requirement for the crew, the various systems on ships are needed to keep pace with the times and become more intelligentized and automated.

For instance, the VS468 multifunctional tugboat has already met the DNV's unmanned cabin on duty requirement. Meanwhile, one respective 10 and 3 cm radars, electronic chart, automatic navigator, echo detector, doppler log meter, electronic gyrocompass, and clinometer have been devised as well. Monitoring and remote control can be set to all pump valves including freshwater, drilling water/ballast water, fuel, brine, and methanol. Moreover, alarm and control system can be offered to safe operation of master and auxiliary equipment, and the engine room "death alarm" function is also configured. And skills in unmanned cabin, automatic steering, computer monitoring, and a series of modern communication navigation equipment have been applied in the towboats which are manufactured by shipyards in Zhenjiang and exported to Egypt (Giron-Sierra et al. 2015).

The patents and literatures of various new icebreakers are summarized and analyzed, and some possible design conjectures of new icebreakers are put forward. The icebreaker innovatively designed the bow of a ship with a narrow top and wide bottom, which allows the bow to be easily extended below the ice. When the icebreaking operation is carried out, the ship tilts forward at a small angle, and the conical structure of the ship's bow underwater reaches below the ice sheet. Through the action of the ship's ballast water system, the distribution of ballast water is changed to make the ship's center of gravity move back. The forward hull generates forces that push the conical structure forward, which impacts the ice in both the forward and upward directions, thus realizing the "skid-type" icebreaking process.

The idea of a semisubmersible icebreaker was first proposed by Vadim Pikeur, a former Soviet engineer, who proposed an icebreaker that could sail on the surface as well as semisubmersible through specially designed reinforced hulls and "comb" icebreakers. The specific icebreaking method is the lower hull reaches the

predetermined depth and then the ballast water is quickly discharged to make it float and break through the ice with the "comb" type icebreaking mechanism. The main structure of the icebreaker is a lower hull equipped with buoyancy module, ballast tank and main and auxiliary equipment, and a tower of about 20 m. The tower is equipped with a bridge, control system, etc. The icebreaking capacity of semisubmersible icebreakers will be greatly improved compared with current icebreakers, and the icebreaking operation of 5-m-thick ice will be carried out. At the same time, because the propeller is under the ice, it can improve the performance of the propeller.

The mission of the fireboat is clear, and it is inevitable that the city port must be equipped with the supporting fireboat. Meanwhile, the focus of the design of the fireboat is mainly to select a reasonable host propulsion, a fire pump drive mode, an excellent performance, advanced and reasonable firefighting equipment, and an excellent hull line with good resistance performance. The future development of fireboats also needs to reflect the particularity of the image of the city government. People's modern aesthetic requirements are constantly improving, and the appearance of fireboats will be very important. In the new situation, modern fireboats have been given a new content and meaning in addition to the necessary fire-extinguishing technology, which means they are used to protect the water environment from pollution.

Definition

Shallow foundations applied offshore are considered as having an embedment depth to foundation diameter (width) ratio less than unity.

Design Approach of Offshore Shallow Foundations

Historically, offshore shallow foundations can either be large concrete gravity bases to fix the giant superstructures, or the steel mudmats used as temporary support for jacket platforms prior to piling. As the offshore oil and gas developments move into deep water, shallow foundations have become more diverse, including bucket foundations used as anchors mooring floating platforms and skirted mudmats as permanent supports for subsea infrastructures such as pipeline end terminations and manifolds (PLETs and PLEMs). Recent upsurge in exploiting offshore wind as a clean and renewable energy resource around the world makes the skirted foundations a more attractive option for the foundations of offshore wind turbines in deep water, either as a single foundation or in a multipod arrangement. A number of different applications of offshore shallow foundation systems are illustrated in Fig. 1. The partial safety factor approach, referred as to load and resistance factor design approach (LRFD), is generally preferred in routine design. To allow the overall reliability of a design to be quantified better, the applied loads to the foundations are generally scaled up by the load factors, and the shear strength of the soil is reduced by the material factors.

General Loads and Soil Parameters

General Loads

The general loads applied to a gravity-based foundation under working conditions consist of

Shallow Foundations, Fig. 1 Application of offshore shallow foundations: (a) GBS (tank-type structure); (b) TLP; (c) jacket; (d) OWT; and (e) subsea mudmats

Shallow Foundations, Fig. 2 General loads applied to offshore shallow foundations

vertical load V , horizontal load H , and moment M (Fig. 2a). The vertical component mainly comprises the weight of the platform and the foundations, whereas the horizontal and moment components are typically due to the environmental forces from wind, waves, and currents. The ratio of M/H indicates whether a structure is prone to sliding or overturning failure. Concrete bucket foundations used for TLPs or the steel bucket foundations in a multipod arrangement are generally subject to tensile loads due to the “push-pull” mechanism (Fig. 2b). For the subsea mudmats supporting PLETs and PLEMs, the loads acting on the foundations typically include the vertical load V , the biaxial horizontal load H_x

and H_y , the biaxial moments M_y and M_x , and the torsion T (Fig. 2c). The biaxial horizontal loads are induced by the thermal expansion and contraction of the attaching pipelines and jumpers, whereas the moments and torsion are generated by the vertical and horizontal eccentricities. The vertical load is relatively small to the ultimate bearing capacity of the foundation, while the torsional and horizontal sliding or the overturning failure generally governs the design.

Soil Shear Strength Used for Design

The relevance of stability calculations depends on the choice of appropriate shear strength parameters. The stress paths in the soil under a foundation

Shallow Foundations, Fig. 3 Simplified stress conditions along a potential failure surface beneath a shallow foundation

are complex. Figure 3 shows that the relevant shear strengths at different locations along a potential failure surface can be approximated to those measured in triaxial compression (TXC), simple shear (SS), or triaxial extension (TXE), which may differ by a factor of two. In engineering practice, most designs adopt an average shear strength in TXC, SS, and TXE conditions to use in standard design approaches. The environmental loading applied to an offshore foundation is cyclic in nature. Therefore, the effects of cyclic loading on the available soil shear strength have to be considered (Andersen and Lauritzen 1988).

Bearing Capacity

Classical Bearing Capacity Theory

Figure 4 depicts a shallow foundation subjected to a point load P . The eccentric-inclined load P is decomposed into a vertical component V normal to the base and a horizontal component H , intersecting the center of an equivalent fictitious rectangle for which the bearing capacity is calculated.

Shallow Foundations, Fig. 4 Load-equivalent transformation

The “effective width” hypothesis was proposed by Meyerhof (1953) for strip foundations to consider the detachment of the foundation due to an overturning moment resulting from eccentricity of vertical load. The concept of an “effective area” has since been developed for other foundation geometries and more complex loading conditions – including biaxial moment (Hansen 1961; Taiebat and Carter 2002), as shown in Fig. 5. The traditional bearing capacity theory calculates the load-carrying capacity of shallow foundations under combined loading by adopting the concept of effective foundation area in conjunction with modification factors for load inclination, and other boundary conditions including foundation shape and embedment, and soil strength heterogeneity (ISO 2016).

Shallow Foundations, Fig. 5 Definition of effective area for various foundation geometry

Undrained Bearing Capacity

The classical approach for predicting the design unit-bearing capacity is conventionally expressed as Eq. (1) for undrained conditions with uniform isotropic undrained shear strength increasing approximately linearly with depth below mudline (ISO 2016).

$$q_d = F \left(N_c s_{u0} + \frac{kB'}{4} \right) \frac{K_c}{\gamma_m} \quad (1)$$

where q_d is the design vertical bearing resistance ($Q_d = q_d A$), F is a correction factor given as function of kB'/s_{u0} , N_c is the undrained plane strain-bearing capacity factor for uniform shear strength ($\pi + 2$), s_{u0} is the undrained shear strength of soil at the foundation base level, and k is gradient of the increase of the undrained shear strength with depth. The superposing modification factor K_c accounts for load inclination, foundation shape, and foundation embedment.

Drained Bearing Capacity

Equation (2) is a general formula for determining design vertical bearing capacity for drained conditions

$$q_d = \frac{1}{2} \gamma' B' N_\gamma K_\gamma + \sigma'_{v0} (N_q - 1) K_q \quad (2)$$

where N_γ and N_q are the drained bearing capacity factors; γ' is the submerged unit weight of soil;

σ'_{v0} is the in situ effective overburden stress at base level; and K_γ and K_q are the correction factors that account for load inclination, foundation shape, and foundation embedment.

Shortcomings of the Classical Bearing Capacity Theory

Shortcomings of the classical bearing capacity approach for application to offshore shallow foundations are illustrated in Fig. 6 and include that:

- The approach uses linear superposition of separate modification factors to account for load inclination and eccentricity. Therefore, the true coupling of horizontal and moment interaction leads to underprediction of load carrying capacity (Fig. 6a).
- The approach uses the effective area method to account for moment which does not allow for transient tensile resistance mobilized by the generation of negative excess pore pressure (Fig. 6a).
- The approach defines the load-carrying capacity by the single equivalent allowable vertical load, V_d , adjusted to account for horizontal load and moment (Eqs. (1) and (2)). The factor of safety determined by this approach cannot reflect the true load path for a foundation (Fig. 6b).

Shallow Foundations, Fig. 6 Shortcomings of the classical theory

Advanced Approach

Failure Envelopes

As an alternative, the failure envelope approach has been recommended by the ISO guidelines (ISO 2016) for calculating the load-carrying capacity of shallow foundations under multidirectional loading conditions. The failure envelope describes a surface in multidirectional load space which defines the combinations of loads causing failure. A load state that falls within a failure envelope is permissible while a load state that falls outside a failure envelope is non-permissible. A load state that falls on the failure envelope indicates a factor of safety of unity, i.e., all available capacity is mobilized.

Benefits of the failure envelope approach over classical bearing capacity theory include overcoming limitations (a) – (c) listed in the last section, specifically that:

- The approach accounts for inclination and eccentricity of loading by defining capacities under pure moment and horizontal loading (which form apex points of the envelope), rather than by adjustment of the vertical capacity.
- The approach allows visual evaluation of the proximity to failure and the factor of safety against any combination of loads, illustrating visually whether a given load is favorable or unfavorable from the direction of the load path relative to the failure envelope.

- The approach does not require the effective area principle since moment capacity is defined directly, and solutions exist for both full tension and zero tension assumptions at the foundation-soil interface (Shen et al. 2016, 2017). The effectiveness of the effective area method has been investigated in Feng et al. (2019).

Additional advantages of the failure envelope methods include that:

- No adjustment is made to the classical bearing capacity theory to consider the effect of torsion. However, the effect of torsion can be determined explicitly by the failure envelope approach (Feng et al. 2014).
- The approach provides an indication of the displacement path at failure through the principle of normality (Bransby and Randolph 1998).

Determination of Failure Envelopes

There are three main methods for determining a failure envelope in three-dimensional coplanar VHM load space or under the more general six degree-of-freedom-loading conditions. In their initial development, the most common approach was experimental (Gottardi et al. 1999). Plasticity limit solutions can be developed for the combined loading problems using a delicate kinematically admissible mechanism within the soil body (Bransby and Randolph 1998; Randolph and

Puzrin 2003). Numerical finite element method has become a more common method to determine the failure envelopes because the pursue of the plasticity limit solutions is generally not straightforward under more complex conditions, including the foundation geometry, the soil conditions and the loading regime, e.g. the six degree-of-freedom loading (Feng et al. 2014).

General Procedures for Applying Failure Envelopes to Design

In-house program can be developed to assist routine design using the published algebraic expressions of the failure envelopes. A procedure for applying the failure envelopes to design of subsea shallow foundations was provided in Feng et al. (2014), as summarized in Table 1.

Undrained Uniaxial Capacity: Fine-Grained Soil
Exact solutions exist for the pure undrained ultimate vertical capacity for a surface strip or circular foundation. For the surface strip foundations, the rigorous value of the vertical capacity factor of N_{cv} ($= V_{ult}/As_{u0}$) is 5.14, whereas $N_{cv} = 5.91$ and 6.05 for smooth or rough surface circular foundations, respectively. The vertical capacity factor has been determined for other boundary

conditions, including the foundation geometry, embedment depth, and the degree of soil strength heterogeneity. The shape and depth factors were derived through finite element limit analyses and finite element analyses (Edwards et al. 2005; Gourvenec et al. 2006; Salgado et al. 2004), where only the uniform soil profile was examined. Analytical solutions of the effect of soil strength heterogeneity were first presented for strip foundations in Davis and Booker (1973). Gourvenec and Randolph (2003) examined the effect of soil strength heterogeneity for strip and circular foundations using finite element analysis, but the embedment was not considered. The coupling effect of the foundation shape and soil strength heterogeneity on the vertical capacity factor has been investigated recently for surface-rectangular foundations by Feng et al. (2017a). Figure 7 shows that as the degree of soil heterogeneity increases the shape factor reduces, becoming less than unity for values of kB/s_{u0} less than about 2. The reduction in the shape effect becomes less significant as the foundation varies from a square to a longer rectangle, since the plain strain condition prevails in the soil beneath a longer foundation.

The undrained ultimate moment capacity of the foundations with zero-tension interface (ZTI) is generally determined by the effective area method. The pure undrained ultimate moment capacity for surface foundations with unlimited tension interface (UTI) can be determined using the upper-bound limit analysis based on the “scoop” mechanism, giving $N_{cm} = 0.69$ and 0.67 for a strip and circular foundation on uniform soil, respectively (Randolph and Puzrin 2003). The effect of soil strength heterogeneity on the moment capacity factor can be described by the quadratic expressions for strip and circular foundations (Gourvenec and Randolph 2003). The coupling effect of foundation shape and soil strength heterogeneity on the moment capacity factor was determined by Feng et al. (2017a).

Pure undrained horizontal and torsional sliding capacity for a surface rough foundation is straightforward. The horizontal capacity factor for embedded strip foundations was derived from the upper-bound limit analyses by Bransby and

Shallow Foundations, Table 1 Design steps for offshore shallow foundations

Step	Details
1	For given foundation geometry, evaluate s_{u0} and nondimensional quantities B/L , d/B , and κ
2	Evaluate uniaxial capacities for vertical, horizontal, moment, and torsional loading
3	Reduce ultimate horizontal, moment, and torsional capacities to maximum values available, according to mobilized (design) vertical capacity, $v = V/V_{ult}$
4	For given angle of resultant horizontal load, evaluate corresponding ultimate horizontal capacity, and similarly for ultimate moment capacity
5	If required, evaluate reduced ultimate horizontal and moment capacities due to normalized torsional loading
6	Evaluate extent to which applied (design) loading falls within H-M failure envelope, and thus safety factors on self-weight V , live loading H , M , T , or material strength s_{u0}

Shallow Foundations,**Fig. 7** Shape factor of vertical capacity as function of aspect ratio and degree of soil heterogeneity

Randolph (1999). An extension of the solution was made for rectangular foundations by Feng et al. (2017b). Torsion is more relevant to the design of subsea shallow foundations. Finnie and Morgan (2004) investigated the torsional capacity of a surface-circular foundation. The torsional capacity factor for surface-rectangular foundations was derived in Murff et al. (2010). The effect of the foundation embedment on the torsional capacity has been systematically investigated for rectangular foundations in Feng et al. (2017b).

Failure Envelopes for Undrained Conditions

Unlimited Tension Interface The pioneer development of the VHM failure envelopes for skirted foundations under undrained soil conditions ignored the physical embedment and often assumed a surface foundation with an unlimited tension interface (UTI) to represent the tensile capacity provided by the foundation skirts. The idealization is appropriated when the soil resistance due to the work done by shearing in the soil above skirt tip level (e.g., due to the disturbance during installation or scour) is negligible. A close-form expression is available to describe the failure envelopes for a circular foundation with UTI on homogenous soil (Taiebat and Carter 2000) (Fig. 8a).

$$f = \left(\frac{V}{V_{ult}} \right)^2 + \left[\left(\frac{M}{M_{ult}} \right) \left(1 - 0.3 \frac{HM}{H_{ult}|M|} \right)^2 \right] + \left(\frac{H}{H_{ult}} \right)^3 - 1 \quad (3)$$

A closed-form expression is also available to describe the failure envelope for a strip foundation with UTI resting on a deposit with a linearly increasing undrained shear strength with $kB/s_{u0} = 6$ (Bransby and Randolph 1998) (Fig. 8b).

$$f = \left(\frac{V}{V_{ult}} \right)^2 - 1 + \left[\left(\frac{M^*}{M_{ult}} \right)^{2.5} + \left(\frac{H}{H_{ult}} \right)^5 \right]^{\frac{1}{2}} \quad (4)$$

where M^* is modified moment parameter given by the expression

$$M^* = M - h_s H \quad (5)$$

where h_s is the height of the rotation of the scoop mechanism above the foundation level.

The size of the normalized failure envelope reduces with the increasing level of vertical load, as indicated by Eqs. (3) and (4). The normalized

Shallow Foundations, Fig. 8 Example failure envelopes for circular and strip foundations under planar VHM loading

Shallow Foundations, Fig. 9 Example failure envelopes for rectangular foundation under six degree-of-freedom loading

size of the failure envelope also depends on the degree of heterogeneity and generally increases with the decreasing degree of heterogeneity of the most common combination of horizontal load and moment acting in the same direction (Gourvenec and Randolph 2003).

The normalized failure envelope for rectangular foundations was proposed by Feng et al. (2017a) for varying soil strength heterogeneity, and under six degree-of-freedom loading (Fig. 9). A general algebraic expression was given to capture coupling effects of foundation and soil strength heterogeneity on the normalized failure envelopes for rectangular foundations

$$f = \left(\frac{M}{M_{\max}} \frac{M}{|M|} \right)^q \left[1 - \alpha \frac{H}{H_{\max}} \frac{M}{|M|} + \beta \left(\frac{H}{H_{\max}} \right)^2 \right] + \left(\frac{H}{H_{\text{ult}}} \right)^2 - 1 \quad (6)$$

where $H_{\max}$ and $M_{\max}$ are respectively the maximum available horizontal and moment capacity by considering the vertical load and torsion mobilization, and

$$q = 3(1 + 0.1\kappa) \quad (7a)$$

Shallow Foundations, Fig. 10 Effect of failure foundation embedment on the shape of VMH failure envelopes

$$\alpha = \text{Min}(0.9, 1.25 - 0.17\chi) \cdot \text{Max}\{0, 1 + \kappa \cdot [0.11 - 0.08\text{Max}(1, \chi)]\} \quad (7b)$$

$$\beta = 0.03\kappa \cdot \text{Min}(3, 5 - \chi) \quad (7c)$$

where $\kappa = kB/s_{u0}$ $\chi = (B/L)^{1 - 4\theta/\pi}$.

When a pure horizontal load is applied at the base of an embedded foundation, the resulting displacement will involve rotation as well as translation. Likewise, if a pure moment is applied at the base of an embedded foundation, the resulting displacement will involve translation as well as rotation. The coupling of horizontal load and moment leads to an oblique failure envelope, and this effect becomes more evident with increasing embedment ratio. The shape of the normalized VHM failure envelopes for skirted strip and circular foundations was proposed in Vulpe et al. (2014). Feng et al. (2014) presented the failure envelopes for the subsea-skirted rectangular mudmat foundation and found that the effect of foundation embedment on the shape of the normalized failure envelopes can be diminished by translating the load reference point to the foundation level (Fig. 10). For skirted rectangular foundations, it was also revealed that the shape of the normalized failure envelopes can be represented by that of surface foundation if $d/B < 0.3$.

Zero-Tension Interface The effective area method adopted by the offshore geotechnical design guidelines for shallow foundations is

reasonable for predicting the loading-carrying capacity for strip and circular foundations with ZTI under eccentric vertical load, i.e., the V-M loading (Taiebat and Carter 2002). The effective area method is also effective for rectangular foundations under V-M loading, with one-way eccentricity, but significantly underestimated the biaxial moment capacity since this method does not consider the potential of the foundation to rotate about the axis of least moment resistance, and the equivalent rectangles derived from the effective area method are rather different from the contact regions (Feng et al. 2019). For combined VHM loading, the effective area method is conservative by ignoring the coupling effect between the horizontal load and moment.

Failure envelopes for surface foundations with ZTI under combined V-M-H loading have been investigated using plastic limit analysis (Houlsby and Puzrin 1999) and finite element analysis (Gourvenec 2007; Taiebat and Carter 2002) for soil with homogeneous undrained shear strength profile.

The failure envelopes for ZTI were compared with the traditional method for strip and circular foundations under coplanar loading conditions (Shen et al. 2016). The failure envelopes for rectangular foundation with ZTI were investigated in Shen et al. (2017) and given by

$$f = \left(\frac{H}{H_{max}}\right)^2 + \left(\frac{M}{M_{max}}\right)^{2-\nu} - 1 \quad (8)$$

Yield Envelope for Drained Conditions

The term yield envelope rather than failure envelop is commonly adopted for the drained bearing capacity. Yield and failure are synonymous for the undrained limit state of a rigid plastic material while the stress dependency of shear strength for a frictional material leads to gradual yield and hardening with increased displacement. The yield envelope for shallow circular foundations under six degree-of-freedom loading is given by Bienen et al. (2006)

$$f = \left(\frac{h_2}{h_0}\right)^2 + \left(\frac{h_3}{h_0}\right)^2 + \left(\frac{m_2}{m_0}\right)^2 + \left(\frac{m_3}{m_0}\right)^2 - 2a\left(\frac{h_3m_2 - h_2m_3}{h_0m_0}\right)^2 + \left(\frac{q}{q_0}\right)^2 - \beta_{12}v^{2\beta_1}(1-v)^{2\beta_2} \quad (9)$$

where $h_2 = H_2/V_0$, $h_3 = H_3/V_0$, $m_2 = M_2/DV_0$, $m_3 = M_3/DV_0$, $q = T/DV_0$, and

$$\beta_{12} = \left[\frac{(\beta_1 + \beta_2)^{(\beta_1 + \beta_2)}}{\beta_1^{\beta_1} + \beta_2^{\beta_2}} \right]^2 \quad (10)$$

where β_1 and β_2 are shaping parameters for the yield surface in the vertical load plane, varying with foundation types and different soils.

Serviceability

Serviceability assessment requires prediction of foundation settlement over design life. The settlement of an offshore shallow foundation comprises an immediate, undrained component, a component due to primary consolidation, and a component of creep.

Immediate Undrained Deformation

The immediate undrained deformation of a shallow foundation is generally estimated based on the elastic theory. Elastic solutions have been derived for a variety of load conditions, boundary value problems, and layered, heterogeneous, and anisotropic conditions. A comprehensive

selection of elastic solutions is provided in Mayne and Poulos (1999). For a homogeneous elastic soil layer, the settlement w of a circular foundation due to a vertical load V is given by

$$w_c = \frac{q d I_F}{E} \quad (11)$$

where I_F is the rigidity correction factor.

For a rigid foundation, the magnitudes of settlement are equal at the center, corner, and edges, whereas, for perfectly flexible circular foundations, the edge settlements are two-thirds of the magnitude of the center-point settlement. For a rigid rectangular or square foundation, a circular foundation with equivalent area is used to determine the settlement. For a flexible foundation, the corner settlement is approximately one-half of those at the center point.

The reliability of the elastic calculations can be guaranteed by selecting appropriate stiffness parameters. Immediate deformation should be computed using the undrained Young's modulus E_u and Poisson's ratio ν_u .

Primary Consolidation Settlement

An estimate of the vertical time-dependent consolidation settlement of a fine-grained layer under an imposed vertical stress can be determined by the following formula:

$$w = \left(\frac{hC}{1 + e_0} \right) \log_{10} \frac{\sigma'_{V0,z} + \Delta\sigma'_{V,z}}{\sigma'_{V0,z}} \quad (12)$$

where h is the layer thickness, e_0 is the initial void ratio, C is the characteristic value of the compression index of the soil over the loading range considered, $\sigma'_{V0,z}$ is the effective overburden stress at the level of a given soil layer, and $\Delta\sigma'_{V,z}$ is the increment of effective vertical stress in a given soil layer.

The compression index, C_c , should be used in the calculation of consolidation settlements of normally consolidated clays. The swelling index, C_s , should be used in the calculation of consolidation settlements for highly overconsolidated clays where the relevant stress range falls on an unload-reload line. The calculation should be

divided into two parts for stress ranges that span the unload-reload and normal compression lines.

Creep

Deformation due to the reduction in void ratio at constant effective stress condition is referred to as creep. Normally consolidated, particularly highly plastic, clays, organic soils, and calcareous soils are generally most susceptible to creep. Creep effects may be largely ignored in most sands, silts, and heavily overconsolidated clays.

Key Applications

Gravity-Based Structures

Gravity-based structures (GBS) rely mostly on their weight and size of their footprint on the seabed to withstand the environmental lateral and moment loading. The first gravity-based platform, Ekofisk I, was installed in the North Sea at water depth (WD) of 70 m in 1973. Skirts are typically fabricated to the periphery of the foundations when the gravity-based structures are founded on seabeds where softer surficial deposits exist. The provision of deep skirts transmits the foundation load to the deeper, stronger soil. Gullfaks C, built in 1989 at a soft clay site in the North Sea (WD = 220 m), was the first deep-skirted gravity base installed under the assist of active suction. Gravity-based platforms were mainly installed in the Norwegian section of the North Sea with the water depth up to 300 m, and offshore Australia where the water depth does not exceed 80 m.

Concrete Bucket Foundations for Tension-Leg Platforms

The experience from the suction-installed deep-skirted foundations led to applying the technology to individual or clusters of small concrete bucket foundations. The first application of the bucket foundations was for the Sonre A tension-leg platform (TLP), followed by the employment for the Heidrun TLP. The water depth for both installations is above 300 m. The bucket foundation systems were designed such that the dead weight

of the concreted foundation templates (CFT) and ballast counteracts the tension in the tethers under calm weather, working conditions. Only during storm conditions is skirt friction and suction underneath the top cap of the buckets relied on to provide resistance to the moment incurred as the platform offsets over the CFT.

Steel Bucket Foundations for Jacket Platforms

Steel-braced jacket platforms are prevalent worldwide, and steel bucket foundations have been used as an alternative to the traditional pile foundations to support the structures. The Draupner E platform was the first occasion that the steel bucket foundations were provided on a jacket structure. A similar foundation solution was employed on the nearby Sleipner Vest SLT jacket. A unique aspect of this foundation system is the reliance on mobilizing tensile capacity in sands through passive suction under the top cap when the foundations are subject to extreme environmental loads.

With the installation of offshore wind turbines (OWTs) heading into deep water (WD > 60 m), it may prove more economical to use bucket foundations, either as a single foundation or in a tripod or quadruped arrangement. The engineering challenge for suction bucket foundation is to ensure the OWTs can resist the wind- and wave-induced forces without unacceptable deflections, and determine the stiffness foundation system for assessing the fatigue life of the OWTs.

Skirted Mudmats for Subsea Infrastructures

Skirted mudmats have been widely deployed onto the seabed to support subsea infrastructures, including pipeline end terminations and manifolds (PLETs and PLEMs), for oil and gas developments in deep and ultradeep water (WD > 1500 m). The mudmat foundations are generally rectangular in plan, consisting of a top plate fitted with peripheral and internal skirts. Deepwater oil and gas developments continue to push the envelope with regard to the increasing weight and size of subsea mudmats and installation water depth. The Gorgon Project in Western Australia installed 20 subsea structures, some close to 1000Te in weight, and in water depths of up to 1350 m.

Shear Strength

Xiaodong Chen and Kai Sun
State Key Laboratory of Structural Analysis for Industrial Equipment, Dalian University of Technology, Dalian, China

Definition

The shear strength is a fundamental property of sea ice. It defines the maximum shear stress that

the ice can bear prior to failure. The shear strength is an important mechanical property since it is involved in the complex stress condition, which is mainly associated with ice-structure interaction.

Scientific Fundamentals

In many cases, ice–structure interaction and ice–ice interaction are subjected to complex stress condition, where shear stress is involved. The knowledge on ice shear strength is required to analysis ice load and ice failure modes. Since ice is a brittle material, there are difficulties to generate pure shear stress without normal stresses.

Testing Methods

To generate shear stresses, three cylindrical rings are applied as loading apparatus. As shown in Fig. 1, two rings work as confinement while the central part moves downward to provide load (Butkovich 1956; Zhang et al. 1995). The ice core sample, therefore, experiences shear force during the loading. In this setup, two shear planes are generated as marked with dashed lines.

Single shear tests have been performed by Paige and Lee (1967) and Dykins (1971) with loading symmetrically over a semicircular surface of an ice core specimen, as shown in Fig. 2. The failure plane was along the length of the core, since the loading direction was parallel to the long axes of the confinement cylinder. To reduce the confinement effect and expansion, relief holes

are designed on the central of the cylinder. Similar apparatus was applied by Ji et al. (2013) with rectangle confinement and specimen.

The main problem of these tests is that both normal stress and shear stress are generated on the shear plane. Undoubtedly, the normal stress influences the determination of the shear stress and shear strength. Especially for the setup without the relief holes, as we shall introduce in the later section, the shear strength from Ji et al. (2013) is higher than the measurement from others. When the ice sample is under shearing, the deformation leads to volume dilation. The volume change is confined by the confining plate and it results in strong normal stresses on the sample as well as the shear plane.

To avoid the influences of normal stresses, an asymmetric four-point bending rig was designed by Frederking and Timco (1984). In this setup, load is applied at four different points on the ice sample with beam shape, as shown in Fig. 3. The shift of top and bottom loading position results in a high shear stress condition in the central of the beam. And the shear failure is expected to appear in this surface. Although the loading arrangement avoids the influences of normal stresses, it has to deal with the bending stresses. Depending on the slenderness (ratio between height and length), the sample may fail in bending instead of shearing. From this point of view, the specimen needs to be sufficient thick. If so, the specimen only fails after reaching significant load and the local crashing at loading point would be another issue (Bailey et al. 2012). Besides, for the combination of bending and shearing, the central of the beam is no longer under pure shear stress neither, compared with previous setups.

Shear Strength, Fig. 1 Double shear apparatus redrawn from Butkovich (1956) and Zhang et al. (1995)

Main Database of Shear Strength

The shear strength of sea ice has not been measured as much as other mechanical properties such as compressive strength, bending strength, tensile strength. The relative few database and the parameter matrix are given in Table 1. The overall strength is between 0.1 and 2 MPa. Although some parameters are missing, most of them are collected from these references. It shows that the variation is significant depending on the testing condition. It is reasonable that the experiments are

(a) Apparatus redrawn from Paige and Lee (1967) and Dykins (1971)

(b) Apparatus redrawn from Ji et al. (2011)

Shear Strength, Fig. 2 Scheme of single shear test. (a) Apparatus redrawn from Paige and Lee (1967) and Dykins (1971). (b) Apparatus redrawn from Ji et al. (2013)

Shear Strength, Fig. 3 Asymmetric four-point loading apparatus redrawn from Frederking and Timco (1984), Frederking et al. (1986), and Bailey et al. (2012)

performed in different location and research group. Thus, efforts are made in order to that the results can be comparable. Aside of the parameters given in the table, the experiment setup may also be worthy to be considered in the evaluation of the shear strength. As we mentioned in the previous section, the sample is in a complicated stress condition, in most experiments, instead of pure shearing. The normal stress from the confinement may influence the final results.

Natural sea ice is consisting of brine, pure ice, air bubble, and solid salt. Since the ice temperature

is close to its melting point, the ice mechanical properties are sensitive to temperature. Besides, when temperature rises up, the brine is diluted by melting pure ice so that the chemical balance is kept. Therefore, the temperature is an important factor of the shear strength. The relation between the shear strength of sea ice and temperature is given in Fig. 4 based on different resources. In general, the shear strength is decreased with increasing the ice temperature. It shows that the shear strength from Ji and Li (Ji et al. 2013; Li et al. 2002) is higher than that from Zhang et al. (1995). It should be due to the former tests that were performed with lateral confinement.

For sea ice, only the solid part carries the shear forces so that brine volume becomes a key parameter to evaluate the shear strength. In Fig. 5, it gives the relation between brine volume and shear strength based on different literatures. Overall, there is significant scatter in the measurements of the shear strength. The physical property of ice itself is relative random and the grain structure varies depending on the weather condition during ice growth. The loading condition as well can influence the measured shear strength due to the unknown normal stresses.

Shear Strength, Fig. 4 The shear strength as a function of the temperature

Shear Strength, Fig. 5 The shear strength as a function of the square root of brine volume

Generally, the shear strength linearly decreases with decreasing the square root of the brine volume. It is reasonable since the higher brine volume the less solid ice to damage. The results from Butkovich (1956) can reach

2.6 MPa and are higher than the others. Although, in his tests, there was almost not confinement at all based on the experiment setup, the loading direction is crossing to the

grain columns. It might be the reason behind the high shear strength since breaking the grains causes significant loads.

Based on previous results, the brine volume, undoubtedly, plays a major role in the shear strength of the sea ice. It is reasonable since only the solid part resists the shear forces. However, as the discussion above, it is very difficult to generate pure shear forces on the shear plane. Normally, the shear plane is accompanied with normal stress depending on the setup design. The nominal elastic modulus is related to loading rate and stress rate. Therefore, the shear strength is also influenced by the stress rate.

In Fig. 6, it gives the relation between the shear strength and stress rate. It shows that the stress rate has very little influence on the shear strength of the tests by Frederking et al. (1986). In their experiment design, the shear forces were generated by a smart design of four-point bending. In this way, the compressive forces have almost no influences on the loading procedure. The shearing may be generated together with bending, but the bending is not sensitive to the stress rate neither. Thus, it seems that the shear strength from Frederking et al. (1986) is independent on the stress rate. In the results from Ji et al. (2011), on the other hand, the shear strength is strongly influenced by the stress rate. If we move back to the experiment setup (Fig. 2b), there was strong lateral confine during the shearing tests. Thus, the influences from compression are taken into account in the shear strength.

Shear Strength, Fig. 6 The shear strength as a function of the stress rate

Key Applications

The shear strength of sea ice draws attention since its potential application in both scientific and engineering circumstances. For the former one, the shear strength is helpful to understand the failure and deformation mechanisms of ice under complex stress states while for the latter one, the shear strength can be an input parameter for structure design.

Compressive Shear Faults

When sea ice moves against with vertical structure, the compression process may dominate the ice–structure interaction. Even under compression, the ice usually fails with an inclined shear crack $45 \pm 5^\circ$ to compressive stress direction, depending on the stress condition (Schulson 2002). In some scenarios, the ice is usually under confinements, especially for the thick ice. For the ice under biaxial and triaxial compression, it may fail with a narrow shear band orientated on a plane of maximum shear. As shown in Fig. 7, it gives the sketches of different shear faults. In the Fig. 7a, the terminal failure is assumed to be caused by plastic flow and the compressive strength is represented by the difference between

Shear Strength, Fig. 7 Schematic sketches: (a) plastic shear fault with a shear crack; (b) Coulombic shear fault with a shear band (Schulson 2002)

Shear Strength, Fig. 8 Structural evolution of P-faulting in granular ice (Golding et al. 2012)

the greatest and the least principle stress. In the Fig. 7b, the failure can be explained in terms of comb-crack mechanism and Coulombic frictional criterion. The shear faults are in terms of P-fault and C-fault.

Based on the main purpose of this section, we focus only on the P-fault, which is dependent on the shear strength. During the P-fault, it can be observed that a shear band appeared on the ice sample as shown in Fig. 8. Golding and others suspect that the process involves local heating and recrystallization (Golding et al. 2012). Since the grain size in the shear band is smaller than the rest, it is reasonable to assume that part of the ice is melted and refreeze in a very short period.

Shear Ridge Formation

Ice ridges can be categorized by the formation process shearing and compression. The shear strength may not be directly applied on ocean engineering, but it is helpful for understanding the formation of ice ridges and makes contribution to the force balance model (Lipscomb et al. 2007). One potential application is the ice forecasting model. In this model, the shear strength takes part in the local stress calculation as a parameter. Although the model usually focuses on a geophysical scale, it could provide environmental parameters for ship navigation and ocean structure operations.

ISO19906 Standard

Shear failure can be a relevant limiting mechanism for which an example is shown in Fig. 9.

Shear Strength, Fig. 9 Ridge shear failure (dashed line shows the displacement of failed ridge) (ISO19906 2010)

When a contact appears between an ice ridge and a structure, the shear failure is one of the potential failure processes. Ice is seldom in a state of pure shear while acting on a structure, as shown in Fig. 9 (ISO19906 2010). Therefore, the shear strength is not usually considered as an independent material parameter. In the design of Arctic offshore structures, the shear strength may be used as a parameter to interpreting full-scale data for the calculation of ice actions.

Definition

MEPC adopted a series of important guidelines at its 63rd session, held from February 2 to March 2, to promote the improvement of energy efficiency of international shipping vessels. The pivotal content consists of two aspects: focusing on the adoption of energy-saving technologies from the construction stage of ships based on technical measures, of which the concrete index is EEDI, and focusing on improving fuel economy and energy efficiency through equipment management and navigation optimization in the operation stage, of which the concrete index is EEOI. In this section, the specific calculation methods of EEDI and EEOI are not discussed in detail, and relevant measures are expounded only around the goal of lowering these two indicators.

Measures to Improve Energy Efficiency at the Design Stage

The application of one or more energy-saving measures in the design and construction of ships can effectively improve the energy-saving level of ships and reduce pollutant emission. A full workflow of various energy transmission processes in ship as a whole system is thoroughly studied by Tillig et al. (2017). In the following, some aspects to increase a ship's energy efficiency from design perspectives are firstly described.

Ship Optimization Design

The key of energy-saving technology of ship is the optimum design of energy-saving ship. It satisfies the ship exploitation conditions, optimizing hull form design and ship form to minimize the ship's resistance and selecting the main engine with low oil consumption to make the overall coordination match, to achieve the optimal configuration of the ship's engines, propellers, and rudders, and thus to improve the ship's propulsion efficiency and reduce the operation cost. Through the hull form optimization, the ship has better fluid lines to reduce its resistance, thus may achieve the higher speed at the same fuel consumption or reduce 8%~15% the ship energy consumption at the same speed.

Bulb Stern Ships

The ship type is characterized by a bulb having a length of 1%LPP~2%LPP and a very narrow width at the stern of the ship at the full load draft. According to the principle of fluid mechanics, the bulb stern is used to generate an equal amplitude wave opposite to the stern wave to reduce the wave height. There are two main functions: one is to absorb wave to make the wave-originated point of the stern wave back. As a result, the diffusion surface of the stern wave is greatly reduced, which reduces energy loss to reduce the ship resistance. And another is to improve the wake flow, as a rectifier, to improve ship propulsion efficiency. At the same time, it can also reduce the excitation force of the propeller, which is conducive to vibration reduction. The main parameters of the bulb stern design are its length, size and shape of its cross section and spherical center, etc. Generally, it is advisable to be located on the center line of the propeller shaft, and its size and shape can be selected according to the ship model test. This ship shape saves main engine power about 7% to 9%.

Bulbous Bow Ships

In $F_n = 0.25 \sim 0.35$ for the designed ship, the adoption of bulbous bow can reduce wave resistance, wave breaking resistance, and bilge-eddy resistance. For this, a bulbous bow is provided on large ships and also on some small ships. Bulbous

bows are shaped in water drops, melon seeds, ellipses, and small noses. The main parameters of bulbous bows, such as length, width, sizes and shapes of cross section, and bulb immersion depth, can be determined according to designed ship types, Froude numbers, drafts etc. Generally, the shape and size of the bulb are optimized by ship model experiment. The wave caused by the bulbous bow and the bow wave can counteract with each other, so as to improve the flow at the forward entrance to achieve the purpose of reducing wave resistance. A bulbous bow can also increase the ship buoyancy, acting as a ballast tank to adjust the ship's trim. Bulbous bows can reduce the total resistance by 8% to 11% when used on large cargo ships and oil tankers and about 6% when used on medium-speed ships and high-speed ships.

Shallow Draft Large Full Ships

Shallow draft large full ships are a kind of ship restricted by the channel and port berth drafts. Their main features: firstly, the deadweight is increased by 20%~30% compared with the conventional ships, the higher the design tonnage, the better the load effect. In general, the deadweight ratio of carriers of 2500 gross tonnage and upward is above 0.67. Secondly, they have high economic benefit, because the ship type has the characteristics of large cargo capacity and shallow draft and can serve as ore carriers, coal carriers, oil tankers, chemical liquid carriers, and replenishing ships for fleet in sea. This ship type also has the advantages of low cost, less investment cost, more operating routes, and more navigable routes, which are widely used at home and abroad.

Construction Optimization and Application of High-Strength Steel

It is mainly to improve the local external characteristics to make the ship structure lightweight. The methods are as follows: selection of appropriate frameworks and frame spacings; application of corrugated bulkheads; selection of appropriate connections between members; determination of the total longitudinal strength of the ship by optimization design; reasonable increasing of the proportion from 30% to 55% of high-strength steel applied to longitudinal members,

decks and longitudinals, top wing tank sloping plating and longitudinals, shells and inner bottom plating and longitudinals, side shell plating, inner hulls, and bottom stringers transverses; reasonable structure arrangement to improve the utilization rate of materials, such as joint type design and reasonable frame spacing; and reasonable structure design, such as the optimized configuration of transverse corrugated bulkheads. On the target ship, the rectangle cargo hold transverse bulkheads are replaced by trapezoidal bulkheads, which can reduce the overall weight of each transverse bulkhead, reducing the number of bottom stiffeners for anti-buckling reinforcement.

Main Engine Type Optimization

Main engines are selected after increasing the diameter of propeller, mainly to downshift the engine to realize the purpose of keeping ship speed unchanged and reducing the fuel consumption rate of main engine, thus to reduce EEDI value of ship and improve energy efficiency (Bailou 2013).

Optimal Configuration of Ship, Engine, Propeller, and Rudder

The optimal configuration of ship, engine, propeller, and rudder is a very complicated technical subject, which involves many technical problems such as ship type, ship's main parameters, power units, selection of propeller, rudder design, etc. To improve the ship's speed, effective measures can be taken to reduce ship resistance, improve propulsive efficiency, and increase engine power. The measures to improve the efficiency of propulsion are as follows.

Design of Large Slow-Turning Propellers

The propeller diameter is usually determined according to the shape of the stern and ship's draft. Increasing the propeller diameter as well as decreasing the rotating speed can improve the open propeller efficiency and increase the thrust deduction factor and wake fraction to improve the hull efficiency. Therefore, to design a large slow-

turning propeller, matching the optimum stern shape is one of the important measures to save energy. On high-speed ships, installation of a large slow-turning propeller will obtain the best propulsion efficiency.

Application of Inboard-Rotating Screws

Domestic studies on an inboard-rotating screw show that the hull efficiency using inboard-rotating screws can be increased about 20% above that using an outward turning propeller. For propellers of MAU type and B type, the hull efficiency can be increased about 2.4%, and the rotation efficiency is improved by 3% to 5%. The mechanism is mainly to produce a kind of reverse oar effect, because the inward turning propeller is opposite to the tangential speed of the incoming flow into the oar disc, then the rotating speed of the propeller is equal to the increase of the rotating speed of the flow, and the increase of the thrust of the child propeller, thus improving the ship propulsion efficiency. If the optimal stern shape is designed skillfully, the wake field can be improved, the wake fraction can be increased, the thrust deduction fraction can be reduced, and the propeller can be operated in a stable and high wake region, then the ship propulsion efficiency can be improved significantly.

Application of High-Performance Airscrews (PBCF Devices)

A PBCF device (also known as the Propeller Boss Cap Fins) has been developed abroad, which has fins on the propeller shaft sleeve cover having the same number as that of the propeller blades and having different shapes depending on the shape of the stern. The main function of PBCF devices is to reduce the vortex generated by propeller rotation to reduce the eddy resistance. This device has the advantages of simple structure, lightweight, and low cost. It is suitable for all kinds of ships, especially for those with a larger propeller pitch.

Application of Boost Wheel Devices

A ship boost wheel device is a device recycling the propeller races to convert some wake energy into additional thrust for the ship propulsion. The

device adopts a roller bearing to support the end of the propeller shaft, which can freely rotate on the propeller shaft to generate additional thrust under the action of propeller wake, thus improving the ship propulsion efficiency. The device is simple in structure and easy to install, disassemble, and maintain.

Positioning Optimization of Propeller Tip Relative to the Hull

The gap between propeller tip and hull surface can be optimized to reduce eddy current effect. For vessels sailing in deep water, it is generally advisable to design propeller tip beyond the hull baseline and make propeller shaft center line and hull horizontal line form proper stern shaft inclination angle (1.5° to 2.3°), which can improve the incoming flow in front of propeller disc and provide sufficient water supply to improve the efficiency.

Application of Rudders with Additional Thrust Fins

A rudder with additional thrust fins is a boost installation for ship energy saving, of which the pushing fins are set at the appropriate positions on both sides of the rudder blade to adjust the angle of incidence of the rudder sides in order to be suitable for the propeller wake flow. In this way, on the one hand, the rotational energy in the propeller wake can be recycled, and on the other hand, part of the lift generated by the thrust fins can be converted into additional thrust. The main parameters for additional thrust fins include length, cross-sectional types, locations, and mounting angles of fins. Thrust fins are installed on some large full-formed single-screw ships abroad, which can save main engine power about 4% to 5%. The thrust fins studied in China have also been installed on more than 20 inland waterway boats, and the energy-saving effect is considerable.

Application of Auto-steerings

After selecting the ship type and power unit as well as the appropriate propellers, auto-steerings may be applied to get the best result.

Optimizing Arrangement of Equipment and Systems

It is mainly to optimize the layout and setting of ballast water operation, piping, and valves from the perspective of economic and convenient use, such as less use of pipelines and valves, and discharge of ballast water by combining pump and gravity.

Speed Design

Traditional ship design is usually optimized for design draft service speed or structure draft maximum speed. However, in the actual operation of the ship, the actual operation state and design point of the ship are generally quite different according to the different types of the ship, different types of goods, different environmental meteorological conditions of the route, and different operation strategies of the shipping company. For example, with most oil tankers, the full load condition will not exceed 50%, and the main engine power is below 50% MCR on average when operating. For container ships, goods are lighter in many cases, and the average operating condition is about 60% to 70% of the full load. According to the operation strategy of the shipping company, the main engine power is only 50% of MCR (MCR is the maximum continuous power of the main engine). Hydrological and meteorological conditions, channel water depth and other restrictions on the vessel equipment and hull surface state, and fuel quality have different degrees of impact on the operating conditions.

The vessel operating condition combination (draft/load, main engine power/speed) and its occurrence frequency are called operation profile. Each shipping company has its own operation profile. Airspeed design according to operation profiles is a comprehensive optimization method with multiple operating conditions, which gives greater weight to the operating conditions with high-operating frequency, so that the energy efficiency of ship operation can be optimized. This airspeed design method is widely studied by the industry and will be applied more and more.

Measures to Improve Energy Efficiency at the Operation Stage

According to the calculation formula of EEOI and relevant literature, the main factor affecting the size of EEOI is the fuel consumption rate of the berthing time during the voyage speed loading rate (Faber et al. 2009).

Speed is positively correlated with EEOI and is most sensitive to its changes. Reducing speed is therefore the most effective way to increase energy efficiency. IMO's priorities include reducing speed. Because of the high oil price at present and the global trade is relatively low, the liner companies are highly competitive, and each ship company has reduced the speed to save fuel consumption, which is objectively beneficial to emission reduction. In addition, the speed increases or decreases in the same proportion, EEOI changes in different proportions, and the influence of growth rate on EEOI is greater. Although reducing speed is most effective for improving energy efficiency, it will also lead to a decrease in transportation turnover per unit of time. In order to ensure the normal transportation of goods, it may increase the shipping capacity, resulting in an increase in total CO₂ emissions. Therefore, the ship's speed should be optimized.

The sensitivity of EEOI to full capacity is second only to speed, and the two are negatively correlated. Therefore, increasing the load factor will play a greater role in reducing EEOI. It is also in the economic interest of the shipping company. The full load rate increases or decreases in the same proportion, while EEOI changes in different proportions.

EEOI is negatively correlated with voyage. EEOI has a low sensitivity to changes in voyage relative to speed and load factor. That is to say, if other factors remain unchanged, the increase of single voyage helps to reduce EEOI, but the change will be more limited. It is worth mentioning that in the calculation of the deadweight, six items, such as personnel and luggage (WPB), total reserves (WR), fuel oil (WF), lubricating oil (WL), furnace water (WBW), spares and supplies (WRS), account for a small proportion of the total displacement. The empirical formulas for the total

amount of fuel oil and lubricating oil furnace water in a ship are all related to the voyage. Therefore, if these small quantities are not neglected, the sensitivity of the voyage factor may vary slightly.

Berthing time is positively correlated with EEOI. This is because ships do not increase turnover when berthed, but CO₂ emissions remain. Therefore, the longer the berthing time, the higher the EEOI and the lower the energy efficiency. The berthing time is mainly the loading and unloading and waiting time at the port, improving the efficiency of loading and unloading at the port can accelerate the turnover, which is helpful for reducing the emission and improving the efficiency. Relative to speed and load factor, EEOI is not very sensitive to berthing time. However, in actual operation, the ship will be attached to several ports, and the use of the ship crane will increase the fuel consumption of auxiliary engines.

The ship's emissions come from the fuel consumption of the auxiliary engine boiler, including maximum continuous power of host (PMCR), engine fuel consumption relation (FM), auxiliary engine average fuel consumption (FA), and boiler average fuel consumption (FB). Therefore, in the future, if manufacturers of marine auxiliary boilers can design relevant marine machinery and equipment with lower fuel consumption and higher efficiency, it will be very beneficial to the improvement of ship energy efficiency. In the daily operation, the shipping company pays attention to protect the machinery and equipment, so that they can achieve the best operating environment, and also save fuel consumption and improve energy efficiency.

In conclusion, measures to improve energy efficiency in the operation process should closely revolve around the above key factors.

From market perspectives, different ways related to increase a ship's energy efficiency and reduce air emissions to comply with IMO regulations have been surveyed by some major classification societies, such as in ABS (2015) and DNVGL (2014). In the following, a few typical measures are presented to show how they can help to reduce the IMO EEOI during a ship's operation/service period.

Routing Planning

For example, multi-port direct transport scheme, the combined operation of trunk and branch lines. The energy consumption and energy efficiency level of the ship fleet should be compared and analyzed. The energy efficiency target evaluation system should be established as the basic basis for evaluating the strengths and weaknesses of each decision-making scheme, and the optimal scheme should be selected.

The main factors, such as supply factors and port factors, which are related to ship energy efficiency and ship utilization efficiency, should be considered. For example, the distance between the basic port and the route and the distance between the voyage and the ship's energy efficiency, the basic port is selected in the port with a relatively concentrated source of goods, which can reduce the turnover of goods and reduce energy consumption. Natural conditions of the port and handling efficiency are the operational efficiency factors that should be considered by owners or ship operators during a ship's voyage planning. Various optimization methods used in the routing planning markets can be referred to Wang et al. (2017).

Many factors, including seasonal factors, should be taken into account in the formulation of schedule and schedule, and economic speed should be adopted from the perspective of energy efficiency and economy of ships. In the operation process of liner ships, the flow of goods between ports is changing at any time. The original confirmed order of docking port and docking should also be adjusted in real time according to the situation, so as to make the ship full load and improve the load rate. According to the loading capacity of the ship, the time schedule or the frequency of ship dispatch should be adjusted in time. The spare time of the ship arriving at the port should be designed according to the specific conditions of a port and carefully planned and arranged by the company so that the time schedule drawn up can be flexible and adapt to the changes of external conditions. The ship should slow down and use the economic speed according to the shipping date, so as to avoid the fuel consumption caused by the

accelerated voyage caused by the delay and shift caused by the overtight design. The reduction of freight volume due to deceleration shall be coordinated by increasing vessels, and the corresponding measures shall be communicated and coordinated with the port side and cargo owner.

Timely Communication

Good early communication with the next port to maximize availability of traffic or berths is conducive to reducing ship lock or berthing waiting time, thus using the best speed in advance and reducing fuel consumption.

Reasonable Scheduling

We should strengthen the management of shipping routes, optimize the resources of shipping capacity and goods supply, reasonably arrange the ships, optimize the ship types, and reduce the operations at intermediate ports. According to the voyage mission plan, the ship should take the factors such as the check of tidal weather channels into full consideration and choose the best time to ship, so as to reduce the frequency of berthing.

Speed Optimization

The main engine power is directly proportional to the three times of the speed, so the ship should choose a reasonable speed according to the importance and urgency of the task. If time permits, the engine power and fuel consumption will be reduced to the third power, which can significantly reduce fuel consumption. Considering the actual operation condition of the marine diesel engine, when the power and speed change, the fuel consumption rate is affected by the quality speed of the air change of the fuel injection quantity and is not a constant value. Generally, the fuel consumption rate is the minimum when the load is 75% to 90%. Therefore, the principle of ship speed optimization is to select the right evaluation approach, taking into account of the navigation route and operation requirements, to analyze and determine the reasonable economic speed for various ship types and ages and find the best

equilibrium point between fuel consumption and speed according to the technical data, such as ship's speed and fuel consumption of main and auxiliary engines.

Application of Economic Routes

Under the premise of ensuring no violation of navigation rules and safety, the actual voyage can be shortened to the maximum extent, but the shortest route may not be the optimal one; especially when sailing across the ocean, the optimal route should be the one that takes into account various factors such as wind flow, weather, and sea conditions. Make full use of the equipment such as the depth finder, and make the best use of ocean currents and tidal currents while avoiding adverse weather effects and strong counter current when external conditions such as climate regulations of the navigation channel allow. Although the use of tidal navigation is an effective method to save energy in operation, this method requires the company to consider comprehensively from the efficiency production arrangement of ships in the freight cycle.

Ship and Equipment Management and Maintenance

Underwater Hull Maintenance

The growth of marine attachments to the hull increases ship resistance. Regular hull cleaning reduces drag and reduces overall fuel consumption. The energy efficiency measures for the hull include hull coating, reducing marine biological adhesion and ship resistance; when the ship has fouling bottom and seriously affects the speed of the ship, it should report to the company in time, and the company should arrange to clean up the ship. Regular maintenance of the hull, regular docking and evaluation of the ship's performance and application of coating to ensure the hull smooth. Check and clean the hull regularly to ensure the cleanliness of the hull and to timely complete removal and replacement of underwater paint to avoid repeated point sandblasting and multiple dock repairs resulting in increased hull roughness.

Host Performance Monitoring and Optimization

The operation and maintenance of main engine may be optimized by monitoring and analyzing its performance data including fuel consumption, operating loads and cylinder wear, e.g. properly adjusting oil supply quantity and oil supply advance angle, checking the cylinder and replacing the piston ring, cylinder liner and gasket by measuring the cylinder explosion pressure and compression pressure and referring to other operating parameters. Oxygen monitoring: The combustion performance of diesel engine can be improved by monitoring and optimizing oxygen content in intake air.

For modification of diesel injection systems: Some disadvantages of traditional fuel injectors are gradually revealed with a great number of ships slowing down. For example, slow running results in poor fuel atomization and even leakage, which causes a certain amount of fuel to enter the cylinder combustion chamber at lower temperatures where it is not fully burned, resulting in oil and carbon fouling and smoke, increased emissions of hydrocarbons and particulate matter, even shorting the life of main engine. The fuel saving and greenhouse gas emission can be reduced by using the spool valve injector or high-pressure common rail electronic injection.

Turbosupercharger matching: Match the supercharger reasonably according to the working condition and load of the diesel engine.

Application of fuel additives: Adding fuel additives can improve fuel quality, improve combustion performance, reduce harmful material emissions, and reduce carbon deposition in cylinder. In addition, there is no need to add device or change engine structure to use fuel additive, so using fuel additive is regarded as a convenient and effective energy-saving and emission reduction measure.

Propeller Maintenance or Update

The surface finish of propeller blade should be maintained, and the damage of edge defect, crack, and wear to the thickness outside the specification should be handled in time. The choice of propeller is usually determined at the design and construction stage of the ship, but the redesign and

selection of propeller should be considered when the conditions of the ship navigation area change. When the propeller is redesigned and selected, the whole of propeller should be considered.

Optimization of Fuel Management and Use

Fuel Oil Addition and Recovery

As far as possible, reasonable fuel loading frequency should be adopted, measures should be taken to prevent leakage from running, and quality and quantity monitoring of the added fuel should be strengthened. Oil, such as diesel oil for cleaning parts, bilge recovery and smear oil in cargo tank, should be effectively recovered, cleaned and utilized reasonably.

Oil Quality Maintaining

To prevent the heavy oil mixed with light oil and reduce the grade of light oil

To avoid or reduce mixing of different batches of oil to prevent chemical reactions from forming large amounts of oil sludge

To shorten storage time of mixed oil to prevent delamination

To closely track the change of fuel quality in use and adjust the heat separation amount according to the oil property

Application of Heavy Oil Technology

On the premise of meeting the requirements of regulations and relevant technical documents concerning the sulfur content of fuel oil for ships, the use of heavy oil technology for ships can be considered to achieve the purpose of energy saving in the following aspects:

- Through the oil supply unit and its heating, heat, insulation, separation, filtration, and hydrophobic system to improve the flow of low-quality fuel and improve the oil quality to achieve the goal of full combustion.
- In the process of using heavy oil, the constant vehicle speed should be controlled reasonably, because the prominent problem of burning heavy oil ships is that the constant vehicle

speed is too low, causing the host engine to operate under low load for a long time and resulting in the combustion incomplete; carbon deposition situation is relatively serious, such as cylinder sleeve wear faster, supercharger pollution, and high-unit fuel consumption rate.

- To manage and make good use of the main facilities and equipment such as the oil distributing unit boiler, clean the boiler regularly, and clean the oil tank regularly.
- The period of oil for the monitoring and testing, the establishment of the ship lube oil use files, to gradually find the rule, to achieve reasonable oil change.

Energy-Saving Awareness, Energy-Saving-Related Training, and Incentive Mechanism

Energy-Saving Consciousness

The cultivation and continuous improvement of energy conservation awareness is an important guarantee for effective implementation of relevant energy conservation measures, as well as an important content of human resource training. Through the cultivation of consciousness of energy conservation, we should be able to achieve the goal of improving the initiative of all members. The cultivation of energy conservation awareness is a long-term process, which cannot be accomplished overnight. First of all, it can start from the small steps that are easy to realize, such as turning off the lights, turning off the air conditioning, turning off the hot water kitchen stove, etc., to form the institutionalized requirements, so as to gradually improve the energy conservation awareness of the whole staff and gradually infiltrate this awareness into the daily work.

Shipshore Energy Efficiency Training

As ship manager, every crew member plays a very important role in higher efficiency and energy saving. Everyone should be familiar with the operation of the ship's equipment and clear about the potential of certain specific equipment in waste or energy saving, so as to manage and operate the equipment well. At the same time, the

crew should also develop a good habit of energy conservation. For example, turning off the pressure fan of floodlight TV has huge energy-saving potential. Each ship has an energy-saving awareness training program for new and returning crew, to create a list of best energy practices, including the main crew on board, and what should be done to save energy.

Incentive Mechanism

The company shall establish a sound energy efficiency assessment and incentive mechanism on relevant internal functions and levels (including ships) for the purpose of better implementation of ship energy efficiency measures.

[Ship design phases](#); [Ship design stages](#)

Definition

The ship design process is an iterative process that needs to meet various technoeconomic requirements, which are partly contradictory to each other. According to the mission characteristics and the completion, the design process can usually be divided into four steps: concept design, preliminary design, contract design, and detail design, where the first two steps can also be named as basic design.

Scientific Fundamentals

Concept Design

It is generally agreed that this is the most important design stage as it translates the mission or ship owner's requirements into naval architectural and engineering characteristics. This stage of ship design is also called feasibility verification, because it further demonstrates whether the design assignment is reasonable, especially for those design assignments without sufficient analysis and demonstration. This part of work is innovative, because the ship design must seek the most economical solution, in which an owner's requirements can be met or not must be considered (Papanikolaou 2002). It requires some experienced

naval architects, who can put forward several feasible schemes of the hull, turbine, and electronics, through drawing and calculation. Preliminary estimations of the fundamental elements of the proposed ship, such as length L , beam B , side depth D , draft T , block coefficient C_B , powering P_B , or alternative sets of characteristics, should meet the required speed range, cargo cubic, deadweight, etc. It includes preliminary light ship weight estimates usually derived from curves, formulas, or experience.

It is worth mentioning that the fundamental elements of a ship have a great influence on the technical and economic performance of the ship, which is the most important work to be solved in ship design (Schneekluth 1998). Whether the fundamental elements are suitable or not is an important factor affecting the overall design and the success of the new ship. Ship's main elements determine the whole aspects of the ship's technical performances and requirements, and various professional technical configurations, in turn, affect the major fundamental elements. Thus, it is a process that needs to iterate and approximate gradually to make sure the ship's fundamental elements are reliable and feasible. The ship design

process can be illustrated by the well-known design spiral, which can better describe the ship design process, originally introduced by J. H. Evans (Taggart 1980; see Fig. 1 below).

The very first effort, concept design, spent about 20 man-days in the 1950s. However, due to the development of computers and software, it takes less time to complete this stage now. Besides, the computer has probably had the greatest influence on the concept design stage (Nowacki 2010). It enables more design variants to be considered quickly, and each variant to be studied in more depth with fewer approximations, so provides more reliable estimates of cost and technical performance. In concept exploration, the naval architect starts with a very broad look at a wide range of options, studies the more promising, and ends up with a single preferred option (Tupper 2013). If the ship owner needs a conventional ship without special requirements, the design process will be much easier for the shipyard, as there exist ships whose information are similar to the new designed ship in size and type, which are usually named as “mother ships.” As a result, the cost will be lower relatively. On the contrary, if the new designed ship does not have information of mother ships to be referenced,

Ship Design Process, Fig. 1 Design spiral, J.H. Evans 1959. (From Taggart (1980))

the shipyard needs to do a lot of calculation. Essentially, the owner's requirements, operating environments, and national and international regulations and conventions must be taken into consideration. Finally, the selected concept design is to be used as a talking paper for obtaining approximate construction costs, which often determine whether to initiate the next level of development, the preliminary design (Taggart 1980). By the end of the concept design, several things should be settled: (1) feasibility to produce a ship to meet a ship owner's requirements within cost, (2) the overall characteristics agreed by ship owner, and (3) good estimate of the cost of acquisition and the through-life cost of the ship.

Preliminary Design

A ship's preliminary design further refines the major ship characteristics affecting cost and performance, which encompass objectives such as length, beam, draft, horsepower, and deadweight, so as to satisfy the owner's requirements and to achieve an optimal solution with respect to a set of economic criteria. This stage requires some major technical documentation of the new ship, including lines plan that is unique to ship design (shown in Fig. 2), general arrangement draft, drawing of midship section, calculation file of structural strength, demonstration files of estimated vessel speed and cargo cubic, and specification list of main equipment and materials. Figure 3 shows a

typical profile of a vessel. Its completion provides a precise definition of a vessel that will meet the mission requirements. Therefore, the outcome of the preliminary design forms the basis for compilation of the shipbuilding contract between the owner and the appointed shipyard.

Any vehicle must comply with relevant standards to ensure its safe operation, and ships are no exception. It is essential that the determination of all technical factors of ship design is subject to compliance with the specifications of various national and international maritime rules and regulations, which are enforced by national and international authorities (flag and port states, IMO) or by an internationally recognized classification society. In case of a lack of regulatory specifications, it is understood that the designed and built ship corresponds to the modern state of the art in shipbuilding science and technology (Papanikolaou 2014).

The combination of concept design stage and preliminary design stage is also known as basic design. Based on the results of the basic design, both the main technical features and the construction cost of an economically efficient vessel can be reliably estimated. Thus, the shipyards may proceed with the preparation of a tender to the interested ship owner. In case the tender is accepted, the more detailed and demanding third and fourth design stage are to be completed (Papanikolaou 2014).

Ship Design Process, Fig. 2 Lines plan of a vessel. (From Huang (2017))

Ship Design Process,**Fig. 3** Typical profile of a cargo ship. (From Huang (2017))

The difficulty of basic design will vary with the degree of departure from past practice. Some ship-operating companies are closely tied to successful previous designs, and they will permit little variation from these baselines in the development of replacement vessel design. If the prospective mission appears to parallel existing operations, this may be a sound approach. Consequently, in such situations, basic design may be limited to examination of minor modifications to dimensions, powering, and arrangements (Papanikolaou 2009). At the other extreme, totally new seagoing missions, such as the ocean transportation of liquefied natural gas (LNG), when first introduced, cause the designer to begin with a blank piece of paper and proceed through rational design engineering with crude assumptions subject to frequent and painstaking revision and development (Huang 2013; Taggart 1980).

Contract Design

The objective of this stage is the completion of the necessary calculations and naval architectural drawings, as well as the drawing up of the technical specifications of the ship's building, which all form indispensable parts of the formal shipbuilding contract between the ship owner and the

appointed shipyard (Taggart 1980). This design stage involves a more precise description of ship's hull form, which is based on faired set of lines, the exact estimation of the powering for achieving the specified speed based on model tests in a towing tank, the theoretical or experimental analysis of the behavior of the designed ship in waves, the analysis of the ship's maneuverability properties, the effect of number of propellers on hull form, details of the ship's structural design, use of different types of steel, spacing and type of frames, design of the ship's auxiliary/supply networks, and so on. Paramount, among the contract design features, is a weight and center of gravity estimate, considering the location and weight of each major item in the ship. The final general arrangement is also developed during this stage. Figure 4 shows the general arrangement of a vessel. This fixes the overall volumes and areas of cargo, machinery, stores, fuel oil, fresh water, living and utility spaces, and their interrelationship, as well as their relationship to other features such as cargo handling equipment and machinery components.

The accompanying specifications delineate quality standards of hull and outfit and the anticipated performance of each item of machinery and equipment. They describe the tests and trials that

Ship Design Process, Fig. 4 General arrangement of a vessel. (From Huang (2017))

shall be performed successfully in order that the vessel will be considered acceptable. A set of drawing, numerical studies, and technical specifications should be developed during contract design, and for more details, please refer to Taggart 1980. These technical documentations shall be examined and approved by the ship owner and classification society as the basis for the construction design or contract signing.

Not everything envisaged in the concept design and preliminary design will work out as planned, and discussions between the ship designer and owner will be an ongoing process. A record must be kept on who made the decisions

and when safeguards were taken to ensure that changes are made only by those with the necessary authority person. The contract design may be carried out by the same group as produced the concept design and preliminary design, or it may be contracted out, perhaps to a potential builder or to some third party. Ideally the same CAD system will be used, and this must include the safeguards controlling design changes (Tupper 2013).

Detail Design

The final stage of ship design is the development of detailed working plans. These plans are the installation and construction instructions to the

Ship Design Process, Fig. 5 Ship construction (<http://www.baidu.com/>)

ship fitters, welders, outfitters, metal workers, machinery vendors, pipefitters, etc. Figure 5 shows the ship construction scenario. One unique element to consider in this stage of design is that up to this point, each phase of the design is passed from one engineering group to another. At this stage the interchange is from engineer to artisan, that is, the engineer's product at this point is no longer to be interpreted, adjusted, or corrected by any other engineer. This engineering product must unequivocally define the desired result and be producible and operable (Huang 2013).

A characteristic of this phase is that, while the generated drawings and specifications are the outcome of studies and work of expert engineers, the subsequent implementation of the designs into practice depends solely on the capabilities of the shipyard's production units, in terms of both hardware infrastructure and human resources (Papanikolaou 2014). When a new ship is built, the actual situation will inevitably be different from the original design. Although the weight and center of gravity had been calculated in detail, it is impossible to be completely accurate. It is also common to change the material or

equipment specifications without affecting the basic performance of the new ship. In this way, the weight, center of gravity, general arrangement, and structure of the ship will be changed. Therefore, after the completion of the ship's construction, the completed drawings should be updated according to the modification during the construction period. Besides, based on the real ship tilting test's results, the designer needs to modify the original relevant calculation results (such as stability, anti-sinking and floating state), complete other tests, and write the report, which are valuable data for ship design and research (Cheng and Pan 1988).

Accordingly, from mission requirements to the design work, although the design of the ship can be divided into several different stages, but each stage is not independent, they are intertwined in a spiral way forward. Certain calculations, drawings, and instructions are required at each stage. The forward stage is the basis of the later stage design, and the latter stage is also the deepening and development of the previous stage work (Watson 1998). However, the four stage of the ship design and the specific content

of each stage are not immutable, which often be different according to the specific circumstances (such as the urgency of the task, the complexity of the products, complete situation of the references, etc.). In some case, there is no clear boundary between each stage. For example, in the ship-type demonstration and protocol specification of some important products, most of the complete technical documentation should be supply in the design stage. All in all, ship design is a complex and hard process; there will be a lot of documentations produced to define the ship for the users and maintainers during the whole design process.

Key Application

The ship design process is a standardized design process that has been accumulated over hundreds of years of experience. Any ship that is to be built must go through this stage, from the most common bulk carrier to high-performance and high value-added LNG ship, such as bulk cargo vessel (shown in Fig. 6), container vessel (shown in Fig. 7), and LNG ship (shown in Fig. 8). This design process is inseparable to the construction of ships. Thus, it applies to all regulated and legally operated ships, including civilian ships and warships.

Definition

Ship electrical design is one of the major parts of ship design. It handles all design issues in ship electrical system to meet the requirements of ship-owner and guarantee ship quality and safety according to specific ship electrical design standards and specifications.

Scientific Fundaments

Background and Brief Introduction

A ship or vessel can be considered as a floating city, which, as a typical town or city, also needs the underlying conveniences to support the life aboard. One of the ship's necessary amenities is the electrical system because most of the marine equipment and other instruments on ships are electrically driven. Thus, there is a considerable demand for an electrical power, which makes a

Ship Electrical Design,**Fig. 1** The SS Columbia

(<https://en.wikipedia.org/wiki/>)

ship electrical system very significant. However, compared with the electrical system on the land, a ship electrical system has the following prominent characteristics (Ma 2009).

1. There are special requirements for the marine electrical equipment due to the harsh environmental conditions on a ship. Namely, the marine electrical equipment is directly exposed to the complex natural environment facing with the high heat, high humidity, low temperature, salt spray, mold, solar radiation, and electromagnetic interference.
2. The ship power system is a typical independent power system with limited capacity. Therefore, it is difficult to ensure an excellent power quality of ship power system with complex load conditions, which make it susceptible to load fluctuations.
3. The ship electrical system has high power density, and a large number of ship electrical equipment are compactly installed in the ship's cabin within a limited space. Therefore, high reliability is required to reduce the number of equipment repairs and replacements.
4. There are interactions and interferences between various electrical equipment due to the narrow space and EMC/EMI issues.

Starting with the earliest records of a commercially available shipboard electrical system which

dates back to the 1880, the electric light system was first installed and operated on the SS Columbia (shown in Fig. 1). The SS Columbia was equipped with 120 incandescent lights, which were distributed on several circuits and powered by four belt-driven 6 kW dynamos (Skjong et al. 2015). The electrical power plants in modern ship have grown in size and complexity with the growing demands on ship sizes, speed, economy, safety, comfort, and convenience. From the original electrical power of a few kilowatts at 120 V, some of today's navy and cruise ships require an electrical load of over 100 MW at a voltage of 11KV or higher. In the meantime, shipboard electrical system design has changed from traditional low-voltage to medium-voltage generation and distribution due to higher power requirements (Patel 2012).

Design of a ship electrical system includes parameters calculation, equipment selection, and electrical schematic design for ship power system, electric motor drive system, lighting system, electric propulsion system, ship interior communication system, radio communication and navigation system, and ship automation system, which should be in accordance with the requirements of shipowner and relevant standards, rules, and specifications to ensure ship quality and navigation safety.

Traditionally, shipboard electrical system design is supported by numerous electrical system

network analyses in accordance with applicable regulatory body requirements. These electrical system analyses are, namely, electrical system load analysis, voltage drop calculations, electrical load flow calculations, electrical short-circuit analysis, and circuit breaker coordination and selectivity study.

The advent of all-electric ships and advances in components, such as the development of high-efficiency, power-dense, lightweight motors, transformers, drives, and other devices, require careful and, in many cases, entirely unique integration into the ship system design and development. These imperatives motivate the use of tools for the system-wide analysis of shipboard electric power systems. In order to perform these analyses, digital simulation of electrical systems is essential. For example, in order to establish the physical laws, governing power system components and their interactions data are collected in large numbers and analyzed to predict the behavior of a system. Digital modeling and simulation are fast, accurate, and convenient approaches for predicting power system behavior. The new technology of electric-driven propulsion power systems requires additional system analyses such as power system dynamic analysis, harmonic analysis, network transient analysis, electric motor drive performance analysis, and extensive modeling simulation of power generation and distribution. These analyses are usually done by the use of computer-aided engineering and design tools (Islam 2004).

As an example, it is necessary to calculate the load factor in ship electrical load analysis. Not all loads are turned on at all times, and many come one after another, each for a short duration of time in a set sequence. Therefore, the required generator capacity in kW is always less than sum total of kW rating of all connected loads. This time diversity in their demand is taken into account by assigning a load factor to each load equipment based on the heritage data on a similar ship built and operated earlier. The *load factor* (*LF*) – also known by other names such as demand factor, diversity factor, utility factor, or duty factor – is defined as the average power over a period of time as a fraction of peak (or rated) power of the

equipment. Thus, the load factor indicates to what extent a specific load contributes to the total load on the generator, which aggregately powers all the connected loads. If the time-varying load power $p(t)$ is expressed in kW over any specific operating period T (e.g., at sea, in-port loading, etc.), then the load factor during that operating period is given by

$$\begin{aligned}\text{Load factor} &= \frac{\text{Average kW load}}{\text{Peak kW rating}} \\ &= \frac{1}{\text{Peak kW rating}} \frac{1}{T} \int_0^T p(t) dt \\ &= \frac{\text{Actual kWh used during } T}{\text{Peak rated kW} \cdot T \text{ in hours}}\end{aligned}$$

Obviously, $LF = 1.0$ for continuously on load, $LF < 1.0$ for intermittent load, and $LF = 0$ for standby equipment. For example, a 10 kW motor used at full load for 4 h and at one-half load for 2 h during a 12-h period on loading days at the port has a load factor of $(10 \times 4 + 5 \times 3) \div (10 \times 12) = 0.42$ during the daytime loading period. During other periods, it may have a different load factor such as zero at night (Patel 2012).

Design Standards

The standards for a ship electrical system design are formal documents, established by a consensus that provides the engineering and technical specifications, rules, guidelines, and characteristics for design, construction, and testing of ship electrical system and equipment. These standards address a range of issues, including various electrical protocols with the aim to meet the design performance requirements, maximize functionality and compatibility, facilitate interoperability, and support people's safety and health on a ship.

There are many groups of standards established and published by different organizations around the world, such as international standards, national standards, association standards, classification society standards, and military standards.

The international standards are developed by the international organizations for standardization, such as the International Electrotechnical

Ship Electrical Design, Table 1 The members of IACS (<http://www.iacs.org.uk/>)

Abbreviation	Name
ABS	American Bureau of Shipping
BV	Bureau Veritas
CCS	China Classification Society
CRS	Croatian Register of Shipping
DNV GL	Det Norske Veritas/Germanischer Lloyd
IRS	Indian Register of Shipping
KR	Korean Register of Shipping
LR	Lloyd's Register
NK	Nippon Kaiji Kyokai
PRS	Polish Register of Shipping
RINA	Registro Italiano Navale
RS	Russian Maritime Register of Shipping

Commission (IEC), the International Organization for Standardization (ISO), the International Maritime Organization (IMO), and the International Association of Classification Societies (IACS) as listed in Table 1. The international standards are usually a reflection of the experiences of industry experts, researchers, consumers, and regulatory authorities, and they contain the common requirements of many countries; one of such standards is the IEC60092-501 standard (Electrical installations in ships-Part 501: Special features-Electric propulsion plant) which was published by the IEC/TC18 (Technical Committee No. 18 of IEC).

The national standards are approved and published by the national departments for standardization. The example of the national standard is the ANS standard published by the American National Standards Institute. Further, the GB standards are the national standards of China issued by the Standardization Administration of China (SAC), and “GB” stands for “Guobiao” which represents Chinese national standard. The mandatory standards are prefixed with “GB,” and the recommended standards are prefixed with “GB/T,” such as “GB/T 29484-2013 Electrical Installations in Ships-Part 503: Special Features-AC Supply Systems with Voltage in The Range of Above 1kV up to And Including 15kV.”

The association standards are developed by special institutes, societies, and association. The

example of association standards is the IEEE standards published by the Institute of Electrical and Electronics Engineers. The IEEE is a historical and influential academic community in the world. Namely, standard formulation and publishing are major activities of the institutes. The IEEE Std-45 (IEEE Recommended Practice for Electrical Installations on Shipboards) is a recommended standard for electrical installations on shipboard which reflects the technological progress of the US ship electrical engineering and has an extensive reputation in the world. In fact, it is usually taken as a reference for the development of other relevant standards.

The classification society standards represent the standards developed and published by the classification societies, which are the nongovernmental organizations that establish and maintain technical standards for the construction and operation of ships and offshore structures. For instance, the “Rules and Regulations for the Classification of Ships” is a standard published by the Lloyd’s Register, which includes the topics about ship electrical system design, such as “main source of electrical power,” “supply and distribution,” and “electric propulsion,” in chapter Electrical Engineering, Part 6.

The military standards are used to achieve the standardization objectives of the military equipment. They are beneficial in achieving the interoperability ensuring the products meet specific requirements, commonality, reliability, cost of ownership, compatibility with logistics systems, etc. For instance, the US military standard is used to achieve the standardization objectives of the US Department of Defense, and it includes the defense specifications (MIL-SPEC), handbooks (MIL-HDBK), and standards (MIL-STD). These documents serve different purposes; namely, military specifications are used to describe the physical and/or operational characteristics of a product, military standards are used to detail the processes and materials to be used to make a product, and military handbooks are the primary sources of the compiled information and/or guidance (<http://www.hansandcassady.org/>). Among those standards, the MIL-STD-1399 is a notable one used for the US ship electrical system design.

The international standards relate to the development direction of advanced technologies and successful experiences in the ship design field. Furthermore, it is necessary to expand the international trade, so employing the international standards can be beneficial for the commonality and interoperability of ship design. Therefore, many countries adopt the international standards, and some countries directly use the international standards as their national standards. The comparison of the requirements for an alternating current distribution system in the IEC60092-101 standard (the IEC standard, “Definitions and general requirements”) and the GB/T 6994 standard (the national standard of China, “Electrical installation in ships-Definitions and general requirements”) is given in Table 2. It can be seen that the data listed in the second column are identical to the data listed in the third column, which shows that the GB/T 6994 standard adopts the same design requirements as the IEC60092-101 standard.

General Design Procedure

The design of a ship electrical system is an important part of the overall ship design, and it can be divided into four stages: concept design,

preliminary design, contract design, and detail design (Huang 2013).

In the concept design, technical designs and scheme demonstration are developed, and main electrical parameters (such as voltage level and frequency), distribution system, main power supply type and configuration of the main communication, and navigation equipment are determined.

In the preliminary design, the optimal technical solution is developed according to the design requirements. The key tasks include (1) evaluation of a whole load power of a ship to determine the capacity and number of generator sets; (2) drawing of the distribution system diagram for electric power, lighting, electrical drive, communication, and navigation system; (3) estimation of a short-circuit current to support the distribution equipment selection; (4) proposing of a preliminary order list of the main electrical equipment (e.g., the equipment for power supply, distribution, lighting, and navigation); and (5) estimation of a major equipment size (e.g., the main switchboard).

The contract design is an important stage in the entire design process, and it is based on the approved preliminary design and technical design

Ship Electrical Design, Table 2 Characteristics comparison of alternating current distribution system (IEC60092-101 at 2002, GB/T 6994 at 2006)

Characteristics	IEC60092-101	GB/T 6994
Voltage tolerance (continuous)	+6 to −10%	+6 to −10%
Voltage unbalance tolerance	7%	7%
Phase to phase voltage unbalance (continuous)	3%	3%
Voltage cyclic variation deviation (continuous)	2%	2%
Voltage transients		
Transients (slow), e.g., due to load variations tolerance (deviation from nominal voltage)	±20%	±20%
Voltage transient recovery time	Maximum 1.5 s	Maximum 1.5 s
Fast transients, e.g., spikes, caused by switching, peak impulse voltage amplitude	5.5U _{nom}	5.5U _{nom}
Rise time/delay time	1.2 μs/50 μs	1.2 μs/50 μs
Harmonic distortion (voltage waveform)		
Total harmonic distortion	Not to exceed 5%	Not to exceed 5%
Single harmonic	Not to exceed 3%	Not to exceed 3%
Frequency characteristics		
Frequency tolerance (continuous)	+5% to −5%	+5% to −5%
Frequency cyclic variation tolerance (continuous)	0.5%	0.5%
Frequency transient tolerance	+10% to −10%	+10% to −10%
Frequency transient recovery time	Maximum 5 s	Maximum 5 s

assignment. The main tasks in this stage are as follows: (1) a load power are further evaluated; (2) a system diagram and a control diagram of each subsystem on a ship are drawn; (3) an arrangement of electrical equipment is realized; (4) a short-circuit current is calculated, and it represents the basis for relevant equipment selection and protection design; (5) selective protection design is realized and the corresponding analysis is conducted; (6) the routes of main power cables are determined; (7) layout diagrams of electrical equipment installed in the cabins are drawn (e.g., wheelhouse and chart room); (8) the ordering list of ship electrical equipment is finished; (9) the outlines of commissioning and trial trip are proposed; and (10) other necessary designs and calculations, such as transient voltage drop and illumination calculations, are completed.

The last stage of the ship electrical system design is a detail design or production design. This stage is based on the technical specifications and the approved results obtained in the contract design stage. In this stage, the complete set of special drawings and technical documents on the manufacture, installation, commissioning, and inspection are compiled combining with the production requirements of a contract manufacturer.

Key Applications

The design of a ship with reasonable technical performance and good economic performance has to be performed in accordance with the ship's purpose, the requirements of shipowners, and relevant rules and regulations. As one of the major parts of ship design, the design of a ship electrical system has become more and more important with the increase in the large-scale, automation, and energy-saving requirements of ships, which have enhanced the interconnections between diverse subsystems on a ship and brought great challenges to the ship electrical system design. Though there are differences in the design of different ship electrical systems, the key tasks of ship electrical design are similar, and they are introduced in the following sections (Huang 2013).

Ship Electrical Design for Ship Power System

The ship power system integrates the power supply devices, power distribution devices, and loads by a certain manner. The ship power system denotes a generic term for all devices and networks on a ship which perform generation, transmission, distribution, and consumption of the electricity. The design of ship power system mainly includes the determination of system voltage, frequency and distribution, selection of power supply devices, design of distribution equipment, power network, and protection.

The ship power supply equipment mainly includes the main generators and main switchboard (shown in Fig. 2). The control and monitoring tasks of the main generators are all implemented by the main switchboard, and the main functions of power distribution are also completed by the main switchboard. Therefore, the design of the main switchboard is an important part of the power system design and a key to guarantee the quality of a ship power system.

The power distribution equipment is in a very close relationship with the ship power grid. The main task of a power distribution equipment design is to reasonably determine the power mode according to the characteristics and capacity of different loads and select appropriate switches, cables, and other needed components.

The ship power system protection design includes the selection of the proper protection devices and strategies to protect the power consumption equipment (loads) that will guarantee the continuity of power supply and improve the survivability of ship power system.

Ship Electrical Design for Electric Motor Drive System

The ship electric motor drive system (e.g., the motor drive system for ship auxiliary machinery, anchor cable, crane, steering gear, etc.) is an important part of ship electrical system which consumes from 70% to 90% capacity of a ship power system. Besides, it reflects the technical level of a ship electrical equipment.

The design of electric motor drive system includes selection of a control equipment of a motor power circuit (including equipment used

Ship Electrical Design,**Fig. 2** Shipboard main switchboard (<https://www.km.kongsberg.com/>)

for motor start, power converter, and control equipment), an auxiliary equipment of a control circuit (telemetry equipment, signal equipment, and alarm equipment) and cables for power and control circuits (including cable type, number of cable cores, and cable cross section), drawing of the electrical wiring diagram of a motor drive system, and determination of the installation and arrangement of control equipment with consideration of safe operation and convenient manipulation.

Ship Electrical Design for Lighting System

Ship lighting system is directly related to the safety of navigation and daily life of the crew. When the ships sail in the sea and go through some ports, the work conditions often change. Therefore, the marine lighting must meet the requirements in different conditions. The marine lighting system can be divided into the main lighting, emergency lighting, temporary emergency lighting, navigational lamps, and signal lamps.

Lighting system should be designed according to the requirements for lighting and navigation defined in the classification rules, such as that of a steel seagoing vessel and the relevant clauses in the SOLAS and “International Regulation for Preventing Collisions at Sea.” For different countries

and sailing areas, the requirement norms and rules can be different, and all of them have to be satisfied.

The design of the lighting system involves the design of a power supply of lighting system and its control. The design mainly includes (1) selection of the optimal number, path, and location of distribution boxes and lighting fixture type, (2) illumination calculation according to the type and arrangement of the selected lighting fixtures, and (3) design of a single line diagram and layout of the lighting system (Zhao 2013).

Ship Electrical Design for Electric Propulsion System

The ship electric propulsion systems have experienced the impressive growth over the last decade. The growth of an offshore exploration is one of the drivers for such a development, but the advances in power electronics and increased sensitivity of fuel costs have also contributed significantly to the technical development and applications of ship electric propulsion system. Compared with the conventional mechanical propulsion system, an electric propulsion system has advantages of simpler design (e.g., the complicated reduction gear which was used to run the ship is omitted), reduction of the onboard noise, fuel efficiency improvement (due to the ability to

constantly maintain an optimal rotational speed that provides good fuel efficiency in the generators used for production of a propulsive electric power), and lower life-cycle costs. The electric propulsion systems are often used on icebreakers and oceanographic research vessels that take advantage of the aforementioned operational benefits and large passenger cruise ships and other ships that emphasize the cost and silent operation.

The typical electric propulsion system (shown in Fig. 3) consists of the propulsion generator, switchboard, propulsion transformer, propulsion motor and its power converter, and relevant control system.

The design procedure of electric propulsion system can be divided into a few steps: (1) determination of electric propulsion scheme, (2) main circuit parameters selection (selection of power, speed, and voltage of a generator and propulsion motor according to the general scheme and propeller parameters), and (3) drafting of the main circuit and control circuit, listing the order information of a major equipment. In general, design tasks mainly include the technical documents and schematic diagram development of the electric propulsion system. Typical technical documentation on a ship consists of the specification of ship electric propulsion system, schematic diagram of the main circuit and control circuit (including various manipulation and automatic control

systems, protection, and signal indications), layout and structure diagram of a main switchboard, electrical wiring diagrams and structure diagrams of a console, control board, and other equipment in electric propulsion system.

Ship Electrical Design for Ship Interior Communication and Signal Devices

The ships interior communication and signal devices perform like the human nervous system, which are distributed throughout the ship cabins, making the entire ship an organic whole. Ship interior communication systems can generally be divided into ship telephone communication systems and ship broadcasting systems. The ship telephone communication systems mainly include three parts, wherein the first part is the navigational command telephone that enables the wheelhouse to communicate with the navigation-related departments, and it is essential to ensure the navigation security. The second part includes the special telephones for several important work sites, guaranteeing the rapidity of communication on a ship. The third part consists of automatic telephones installed for the communication in daily work and life.

On the other hand, to get the information on the operation of various kind navigation mechanisms, the telegraph system, indicators, foghorns, and signal control devices should be installed in a

Ship Electrical Design,
Fig. 3 Simplified single line diagram of the power plant with a propulsion system
(<https://proyectosnavales.com/>)

ship control equipment. Besides, the general alarms, fire alarms, fire detection alarms, radio intercoms, and shared antenna systems should be designed and installed such that to transmit the acoustic-optic signals and instructions.

Ship Electrical Design for Radio Communication and Navigation System

The radio communication can be a conventional radio communication or satellite communication, which is used for distress alert, search, rescue work, daily public communication, and business contact. The design of a ship radio communication system mainly includes layout diagram of the radio communication equipment, layout diagram of antennas, layout diagram of radio communication equipment in ship cabins, and the detailed list of the spare parts according to the specifications and shipowner's requirements.

The mission of a ship navigation system is to ensure the navigation safety of maritime transport and marine engineering ships and guide the ships to reach their destinations on a scheduled route accurately. Marine navigation equipment mainly consists of a compass, an adaptive autopilot, echo sounder and speed log, a rudder angle indicator, GPS receiver, foghorns, anemometer, and automatic identification system (AIS). The design of a

ship navigation system includes the creation of a navigation equipment scheme (according to the ship navigation area, specifications, shipowner's requirements, etc.), selection of a ship navigation equipment type, drawing of the equipment system diagram, and equipment layout.

Ship Electrical Design for Ship Automation System

The ship automation system refers to the automation control system and monitoring system which are composed of various instruments, elements, and computers. In this kind of system, the operation of a machine is supervised and controlled by a self-regulating mechanism which senses the machine performance and provides a rapid and accurate analysis and record on the related parameters. For instance, a machine can be regulated to the desired state or give an alarm to a malfunction without human interference by its automation control system. An automation system contributes to the reduction of the amount of improper operation of the engine and improves the safety and reliability of navigation, which becomes more and more important in the ship electrical systems.

The design of a ship automation system includes an engine room automation (shown in Fig. 4) design, navigation automation design,

Ship Electrical Design,

Fig. 4 Engine control room console (<http://ships.fish.hokudai.ac.jp/>)

and design of automation for loading and unloading. Engine room automation design includes the design of the engine room monitoring and early warning, main engine remote control, and automatic power station.

For instance, in the design of an engine room monitoring alarm system, it is necessary to take into account the automation mark of ship classification, as well as electromagnetic interference and cable type and clearance. The design of all marine automation systems should obey the rules, standards defined by special organizations, such as IMO (International maritime organization), local authorities, and IACS (International Association of Classification Societies) and the classification societies.

Definition

Lofting

Is a drafting technique to amplify the design drawing drawn with a certain ratio into a 1:1 full-scale drawing (or a 1:10 or 1:5 ratio drawing), and to use it as the basis for steel blanking and processing of the hull members (Liu et al. 2011).

Manual lofting

Includes full-scale lofting based on scale drawing and ratio lofting based on 1:10 (or 1:5) scale drawing.

Mathematical lofting	Is the technique to use mathematical equations to define the hull lines or the molded base, to establish a mathematical model, and to complete the hull lofting with a computer.
The content of hull lofting	Includes theoretical model line of hull lofting, frame line lofting, lofting of structural line, hull member development, and provision of information for the subsequent procedures.
Hull member marking-off	Is a technique to draw (print) cross lines and processing lines of a member on the flat steel plate and profile according to the member template, sketch, sample rod, and data provided by lofting. It is also necessary to arrange patterns of various member drawings reasonably on the materials in order to save materials and labor, and this procedure is called nesting (Liu et al. 2011).

smooth and fair. The line drawing could be used as the basis in all procedures in hull construction.

Theoretical model line lofting is a process to conduct the 1:1 full-scale lofting according to the station line of 1/10 or 1/20 of the ship length (the length between perpendiculars) with the lines drawing provided by the design department, so as to achieve the smoothness and correction of the three-sided projection of the hull lines drawing (Xu 2011).

1. Drawing of the lofting graticule: The graticules in the lines drawing are the projection lines of each group of hull lines on the corresponding projection surfaces and are the base for measuring the size in line lofting. Methods of drawing graticules include plumb line method, square gauge method, theodolite method, laser theodolite method, etc. (Fig. 1)
2. Drawing of the camber curve: The deck camber at the midship cross section is the largest, and its length gradually decreases toward the bow or stern. The curvatures of the camber curves at each cross section of the deck are the same as the curvature at the midship cross section, so only the camber curve at the midship cross section needs to be given and be used as the criterion to determine the shapes of deck camber at each cross section (Fig. 2).
3. Drawing of the deck center line: Generally, the offset of the deck center line is not given, in the lines drawing, but is instead obtained according to the offset of the deck side line and the height of the round of beam at the widest (breadth molded) point of the deck. When the camber

Scientific Fundamentals

Hull Line Lofting

Line lofting is conducted in the initial stage of the hull construction, so that the design could be reflected and some unreasonable offsets could be corrected and perfected to make the hull lines

Ship Hull Lofting and Marking-Off,

Fig. 1 Graticules drawn with the laser theodolite

Ship Hull Lofting and Marking-Off, Fig. 2 The offset table of the deck camber curves

Ship Hull Lofting and Marking-Off, Fig. 3 Drawing of the deck center line

- curve and the deck sideline are drawn, the height of the deck center line can be obtained (Fig. 3) (Liu et al. 2011).
4. Theoretical model line of hull lofting also includes the lofting of waterlines, buttocks, body lines, bulwark top lines, etc., and the hull line drawing could be considered in theoretical wrap lofting.

Frame lines lofting is a technique to insert different frame lines in the sheer plans and half-

breadth plans according to the actual frame positions based on the theoretical model line of hull lofting, with the consideration of the given frame spaces in the drawings, and then to draw the frame body plan on the midship cross section according to the mutual projection relationship of the three basic projection surfaces (Fig. 4).

Lofting of frame lines at the screwshaft outlet is a technique to not only ensure the smoothness of the axle casing itself, but also ensure the smooth connection between the axle casing and

Ship Hull Lofting and Marking-Off, Fig. 4 Lofting of frame lines

the curved hull surface at both longitudinal and transverse levels. Usually, the smoothness could be achieved and examined through the creation of longitudinal oblique section, which is also an important means to obtain the radius of a circular arc (Fig. 5).

Lofting of Structural Line

Structure line lofting refers to the drawing of the theoretical projection lines of the longitudinal and transverse hull members and shell plating cross junction lines in the frame body plan according to the basic structure drawing, midlength section plan, shell-plating expansion plan, structure plan of bow and stern, block division plan, etc. provided by the design department (Ji 2005).

Lofting of the longitudinal members is a technique to draw the projection of the intersecting lines of longitudinal members with the molded hull surface and frame cross sections in the frame body plan. In the frame body plan, the perpendicular line segments between upper edge lines and lower edge lines, and between outer edge lines and inner edge lines, are the frame section lines of the longitudinal members. The shape enclosed by the two edge lines and the frame section lines at both bow and stern is the projection shape of the certain longitudinal member in the frame body plan (Fig. 6).

Shell plating cross junction line lofting is the technique where the shell plating cross junction

lines are finally arranged after the structural line lofting is completed in the frame body plan. Each plate may have a special name associated with its position on the hull. The plates are named after codes, usually arranged in alphabetical order from the centerline to the sides of the ship. The reasonable arrangement of plate junctions is closely related to the appearance of the ship, the utilization rate of steel, the processing of parts, the erection of sections, the welding technology, and the quality of hull construction.

Hull Member Development

The process of finding the true shape of a curved surface which cannot be shown in the projection drawing, spreading it out on a flat surface, as well as finding the true shape of the plane member which only has a projection in the frame body plan is referred to as development (Li et al. 2006).

The purpose of hull member development is to calculate the number and specification of the steel plates for the whole ship for drawing up the marking-off from sketches and the template to facilitate the marking-off on the flat steel plates.

When using the frame body plan to develop hull members, the three elements of development should be mastered, namely, to find the actual length of projection line, to find the curvature of frame (commonly known as the “brunt”), and to determine the datum line.

Ship Hull Lofting and Marking-Off, Fig. 5 Lofting of frame lines at the screwshaft outlet

Hull longitudinal members could be categorized into two types: first, frame section perpendicular to the frame line; second, frame section perpendicular to the base line. The two types of longitudinal members could both be developed with mean normal method, in which the projection lines of the datum lines of the members to be developed are first drawn in the frame body plan, then the actual lengths of the member-longitudinal seams and the datum lines are found, and finally the hull member development drawing is drawn based on the datum line development (Figs. 7 and 8).

The center spot-squaring method used to develop hull plates is one type of mean normal method. In the frame body plan, if the frame chord lines of the plate are parallel or approximately parallel to each other, then a perpendicular line of the chord line could be drawn through the

midpoint of the middle frame line, intersecting with frame lines. This perpendicular line is called cross line (or cross hair) (Huang 2013).

The geodesic line used to develop hull plates is the shortest curve connecting two points on a curved surface. If the curved surface is developable, its geodesic line in the development drawing is a straight line. However, usually, the hull surface is undevelopable, with a mild curvature degree, and its geodesic line can be approximately regarded as a straight line in the development drawing and be used as a datum line to facilitate the development of hull plates.

The propping line used to develop hull members is a diagonal line added to each quadrilateral, which is approximately considered to be a straight line after development. The diagonal lines can “prop” the quadrilateral and set it into a unique fixed shape in making development drawing.

Ship Hull Lofting and Marking-Off, Fig. 6 Lofting of longitudinal members

Templates and Marking-Off

After the hull member development, based on developed shapes of each hull member, various sketches will be clearly drawn and various templates and mock-ups will be nailed with high precision, as the construction basis and quality standard for marking-off, processing, erection, and inspection (M 2012).

Templates can be categorized into different types by different criteria. By their usages, there are templates for marking-off, section mold, templates for assembly marking, templates for assembly angular, etc. By their spacial shapes, there are flat templates and stereotemplates (mock ups). By production materials, there are wood templates, flat iron templates, plastic templates, asphalt felt templates, cardboard templates, sheet steel templates, etc. By their generality, there are fixed templates, flexible templates, etc. (Fig. 9)

In the production of templates, the edge line of the curved side of the mold is the line of a certain frame on the plate. A set of such triangular templates will be produced according to each frame line of the plate to be processed. When being used, the triangular templates will be placed in their corresponding positions as indicated in the frame body plan (Figs. 10 and 11).

In the production of the mock-up, the mock-up is a curved template produced in the form of a fixed three-dimensional frame, which is equivalent to a three-dimensional skeleton cut off from the hull and connected to the plate. The curved surface of the mock-up represents the theoretical surface of the hull.

The cutting method of the mock-up base level includes the cutting perpendicular to frame section (tangent template) and the cutting not perpendicular to frame section (chamfering template).

Ship Hull Lofting and Marking-Off, Fig. 7 The development of the untwisted bottom-side girder

Sketches for marking-off refer to the sketches that can replace the template record and reveal the drawing information. The sketches have the advantages of saving material for template making and of being restored easily, thus being suitable for small-batched and simple-shaped hull members.

While drawing a sketch, first, the Cartesian coordinate system is determined on the drawing paper (generally, the developed straight directrix is used as the horizontal axis). The member shapes are not necessarily drawn strictly in proportion, where based on the basic shapes shown, the accurate graphics are determined through marking the dimensions. The sketch should also contain the necessary marks, symbols, and instructions.

Marking-off is the drawing of cross lines and processing lines of the member on the flat steel plate and profile, according to the member templates, sketches, sample rods, and data provided by lofting.

Manual marking-off is divided into two major types – marking from templates and marking from sketches.

Marking from templates is the technique to directly draw the actual contour lines, member setup lines, reference lines for inspection, surplus lines required, etc., of the hull members on the steel or profiles by means of templates and to make necessary marks, symbols, etc. In order to retain these lines and marks, the permanent marks must be drawn with colored paint, or be carved with a punch or chisel, etc.

Marking from sketches is the technique to reproduce the actual shapes by means of drawing on the steel plate, based on the basic shape and precise dimension recorded in the sketch. The basic requirements are the same as those of the template marking-off (Fig. 12).

Optical projection marking-off refers to the procedure where, based on proportional lofting, after nesting, the developed member graphics are

Ship Hull Lofting and Marking-Off, Fig. 8 Development of twisted shell-side-longitudinal girder

Ship Hull Lofting and Marking-Off, Fig. 9 Flexible triangle templates

Ship Hull Lofting and Marking-Off, Fig. 10 The production of triangular templates

Ship Hull Lofting and Marking-Off, Fig. 11 The use of templates to test curved plates forming

drawn into an accurate projection base map or photographed into a projection film with a smaller proportion, then enlarged with the optical projection-amplifying device and projected into a 1:1 member pattern on the steel plate, and finally the projected lines of the member are manually marked off.

Electroprinting marking-off refers to the procedure where, based on optical projection

marking-off, the image of the member is projected with an amplification of 1:1 onto the marking-off steel plate covered with photoconductive powder with negative charge, so as to achieve exposure, development, and marking, leave the stitch of the marking-off, and thus complete the automatic marking-off.

Automatic nesting refers to the procedure where several parts of different shapes are

Ship Hull Lofting and Marking-Off,

Fig. 12 Marking-off from sketches for hull plates

Ship Hull Lofting and Marking-Off,

Fig. 13 Automatic nesting drawing

arranged in sequence on a set of rectangular steel plates according to the nonoverlapping layout requirements. The nesting diagram generated by the automatic nesting software is further optimized and corrected manually, and the result is processed by the computer, and the NC-cutting program is output for the use of NC-cutting machine (Fig. 13).

Hull-Mathematical Lofting

Hull-mathematical lofting is the use of the mathematical equation to define the hull lines or the hull surface, so as to establish a mathematical model and to complete the hull-lofting work through the high-speed calculation of the computer.

In the hull 3D-fairing calculation, according to the calculation sequence and calculation method arranged in advance by software, the drawing of hull lines, the offset table, and the matching relationship, between the shapes of the bow and stern and the middle of the hull, are all converted into

data in a certain format required for 3D-fairing calculation sequence and sent to the computer in the prescribed sequence.

The shell plate development calculation is carried out after the 3D fairing of hull lines, interpolation-producing frame offsets, and the hull structure ranking. Its main tasks are to generate the shell-plating longitudinal seam, to calculate developed plate parts, to provide various data charts and NC-cutting data required for the processing of the plate parts, and to provide data and information for the management of shipbuilding projects.

The mathematical lofting of the hull structure is to use the computer to generate the hull structure parts, and create the part drawing, the part nesting drawing, the NC-cutting program, and the data for processing and production management. The mathematical lofting of the hull structure includes at least the following three parts: structure line generation, part generation, and nesting (DM et al. 2015).

Conclusion

Ship hull lofting and marking-off are highly technical, difficult, and precise techniques. It is not only the first process of hull construction, but also provides a variety of accurate and reliable construction basis for subsequent processes of hull construction.

Ship Loses Restoring in Waves

► Pure Loss of Stability

Ship Machinery Design

Guo-Yong Jin and Tian-Gui Ye
College of Power and Energy Engineering,
Harbin Engineering University, Harbin, China

Definition

Ship machinery mainly includes propulsion system, auxiliary power plants, and other auxiliary

machinery. Ship machinery design is one of the important branches of ship design, which is carried out through a specific process to guarantee functional stability, reliability, controllability, maintainability, and operational efficiency of ship. Ship machinery design is currently based on prescriptive regulations embodied in SOLAS and on rules issued by classification societies.

Scientific Fundamentals

Composition of Ship Machinery

Main Propulsion Devices

Ship propulsion plants are the most important part of the ship machinery. Their function is to transmit power from the main engine of the ship to the propeller through transmission mechanism and shaft system and at the same time transmit the thrust generated by the rotation of the propeller to the hull. Ship propulsion plants generally include the main engines, the transmission mechanism, the shaft system and the propeller, etc., as shown in Fig. 1.

The form of power plants of modern ship can be divided into five categories: diesel engine propulsion power plants, steam turbine propulsion power plants, gas turbine propulsion power plants, nuclear power propulsion power plants, and combined power propulsion plants (Li 2010).

Generators

Generators are the main source of electricity for the motor drive of many auxiliaries, deck machinery, lighting, ventilation, and air conditioning equipment. A constant supply of electricity is essential for safe sailing and machinery operation, and therefore, the standby or additional capacity is necessary together with the emergency supply equipment. In the event of a main generating system failure, an emergency supply of electricity is required for essential services. This can be supplied by batteries. Batteries are usually served as the emergency supply, but most merchant ships have emergency generators. Emergency generators are generally diesel driven and located outside of the machinery space (Jiang 2014).

Ship Machinery Design, Fig. 1 Schematic diagram of propulsion plants: (1)main engine, (2) clutch, (3) gear box, (4) intermediate shaft, (5) bearing seat, (6) propeller shaft, (7) propeller. (China Maritime Service Center 2008)

Boilers

Boiler in a variety of forms can be found on different types of ships. If the main machinery is steam powered, one or more large water-tube boilers will be fitted to produce steam at very high temperatures and pressures. On a diesel engine ship, a smaller boiler (usually fire tube type) will be fitted to provide steam for other ship devices (Zhao 2012).

Steering Gears

The direction of the ship is controlled by the steering gear. As the ship moves in the water, the angle of the rudder at the stem determines its direction of movement. Modern ships are so huge that moving the rudder necessitates the use of hydraulics or electrical power. The steering gear provides a movement of the rudder in response to a signal from the bridge. The total system may be considered to be made up of three parts: control equipment, a power unit, and a transmission to the rudder stock. The control equipment conveys a signal of desired rudder angle from the bridge and activates the power unit and transmission system until the desired angle is reached. The power unit provides the force to drive the rudder to the desired angle. The transmission system is the means by which the movement of the rudder is accomplished (Jiang 2014).

Windlasses

The windlass is a usual anchor handling device used to handle both anchors. A new type of windlass, particularly used on larger vessels, is the split

windlass where a machine is used for each anchor. There are some variations in detail design of cable lifters and in their drives. Due to the low speed of rotation of the cable lifter and heaving anchor, a high gear reduction is needed when the windlass is driven by a high-speed electric or hydraulic motor. This is generally obtained by using a high ratio worm gear followed by a single step of spur gears between the warp end shaft and cable lifters. Alternatively, multi-steps of spur gears are used. Capstans with this type of equipment is situated below deck, and the cable lifters are mounted horizontally (Jiang 2014).

Due to the limited number of words, this article only briefly introduces the main auxiliary machinery on board. For more detailed introduction, please refer to *Marine Auxiliary Machinery* written by McGeorg (1995).

Ship Machinery Design Requirements

1. Principal requirements

Economical operation: The overall economical performance of the power plant should be designed to be as better as possible, and the operating cost of the entire ship should be as little as possible.

Reliability: The selection of equipment and the design of systems should be highly reliable, with necessary backup or redundancy.

Manipulability: In order to obtain convenient operation, the use of equipment and systems should be as simple as possible.

Maintainability: The structures of the equipment and the layouts of the piping system should be easy to maintain.

Economical construction: The cost should be as little as possible, and the construction should be simple.

Weight and size target: The weight of the ship's machinery should be as light as possible, and the space occupied by the machinery should be as small as possible.

Vibration and noise level: The vibration and noise should be as small as possible (CSSC 1999).

2. Specific requirements

Meet the requirements of the power plant stated in the mission book or specification book or contract book.

Meet the requirements of the overall performance of the ship on the power plant.

Meet the requirements of the classification society on the ship.

Meet the relevant regulatory requirements of the flag state.

Meet the requirements of the international conventions and regulations.

Meet the requirements of the waters and ports involved in the navigation.

Meet the system design requirements specified or recommended by the equipment manufacturers (CSSC 1999).

Main Propulsion Devices Design

On modern civil merchant ships, the most popular power plants are diesel engine ones, and a small part are steam turbine ones (on a few LNG ships). Gas turbine propulsion power devices, nuclear power propulsion power devices, and combined power propulsion devices are mainly used for military ships, currently not used on civil merchant ships (CSSC 1999). So we focus on the diesel engine ones when designing main propulsion plants.

Main Propulsion Devices Evaluation Indexes

Technical Indexes The rated power of the main engine required by unit DWT and unit ship speed P_a (kW/(t * kn)) is:

$$P_a = \frac{P_{me}}{DWT * V_s}$$

where P_{me} is the rated power of the engine (kW), DWT denotes the ship load capacity (t), and V_s is the ship service speed (kn).

The weight of unit main engine power g_{me} (t/kW) is:

$$g_{me} = \frac{G_{me}}{P_{me}}$$

where G_{me} is the mass of main engine (t) and P_{me} is the rated power of the engine (kW).

The weight of unit power plant power g_{pp} (t/kW) is:

$$g_{pp} = \frac{G_{pp}}{P_{me}}$$

where G_{pp} is the total weight of power plant (including main engine, auxiliary machinery, shaft system, boiler, piping system, etc.).

The relative weight of the main engine α_{me} is given as:

$$\alpha_{me} = \frac{G_{me}}{DWT}$$

The relative weight of the power plant α_{pp} is written as:

$$\alpha_{pp} = \frac{G_{pp}}{DWT}$$

Area saturation K_{er} (kW/m²) is defined as:

$$K_{er} = \frac{P_{me}}{S_{er}}$$

where S_{er} is the area occupied by the engine room (m²).

Daily fuel consumption of the main engine G_{FOC} (t/d) is given as follows:

$$G_{FOC} = 24 * 10^{-3} * P_{CSR} * g_{CSR}$$

where P_{CSR} is the power of main engine at CSR (continuous service rating) (kW) and g_{CSR} is the fuel consumption rate of main engine at CSR (kg/kW*h).

Daily fuel consumption of the ship $G_D(t/d)$ is:

$$G_D = G_{\text{FOC}} + G_{\text{Gd}} + G_{\text{ab}}$$

where G_{Gd} is the daily fuel consumption of generators (t/d) and G_{ab} is the daily fuel consumption of boilers (t/d).

Total fuel consumption per nautical mile $G_n(t/n \text{ mile})$ is:

$$G_n = \frac{G_D}{V_s}$$

where V_s is the ship speed (kn).

Performance indexes Maneuvering ability: the ability of the power plant to quickly change operating conditions, which is usually indicated by the length of time for starting, acceleration, reverse, and parking.

Reliability: the ability of the power plant to work normally and stably during the specified maintenance, repair, use conditions, and periods. Redundancy theory and techniques should be used to maintain the propulsion and power supply of a power plant when failures or damages occur in one or more components of its equipment.

Automation degree: The level of automation and remote control of mechanical and electrical equipment in the engine room. It is generally divided into two categories: manned engine room and unmanned engine room.

Control of noise and prevention of harmful vibrations: the ship's power plant must meet the control criteria of the vibration and noise (CSSC 1999).

Selection of Main Engine

Selection of a suitable main engine to meet the power demands of a given project involves proper tuning in respect to load range and the influence of operating conditions which are likely to prevail throughout the entire life of the ship (Wärtsilä NSD Switzerland Ltd. 1998).

Every engine has a layout field within which the power/speed ratio can be selected. It is limited by envelopes defining the area where 100% firing pressure (i.e., nominal maximum pressure) is

available for the selection of the contract maximum continuous rating (CMCR). Contrary to the "layout field," the "load range" is the admissible area of operation once the CMCR has been determined (Wärtsilä NSD Switzerland Ltd 1998).

In order to define the required CMCR, various parameters such as propulsive power, propeller efficiency, operational flexibility, power and speed margins, possibility of a main-engine driven generator, and the ship's trading patterns need to be considered (Wärtsilä NSD Switzerland Ltd 1998).

Selecting the most suitable engine is vital to achieving an efficient cost/benefit response to a specific transport requirement (Wärtsilä NSD Switzerland Ltd 1998).

Transmission System Design

The transmission system transmits power from the engine to the propeller. It is made up of shafts, bearings, and the propeller itself. The thrust from the propeller is transferred to the ship through the transmission system (Zhao 2012).

The different components in the system include the thrust shaft, the intermediate shafts, and the tail shafts. These shafts are supported by the thrust block, intermediate bearings, and the stern tube bearing. A sealing arrangement is provided at both ends of the tail shaft with the propeller and cone completing the arrangement (Zhao 2012).

The task of the shaft system design is to determine the position of the propulsion shaft and the size and material of each part. Shaft system design is a process that requires repeated adjustments. The steps of the shaft system design are shown in (Fig. 2).

According to the requirements of the classification society, the basic diameter of the shaft is calculated by the following formula:

$$d = F * C * \sqrt[3]{\frac{P_e * \left(\frac{560}{\sigma_b + 160}\right)}{n_e}}$$

where d is the basic diameter of the shaft (mm), F is the propeller coefficient, P_e is the shaft transmission rated power (kW), n_e is the rated speed (r/min), σ_b is shaft material tensile strength

Ship Machinery Design, Fig. 2 Shaft system design steps. (CSSC 1999)

(N/mm²), and C is the design characteristic coefficient.

If the shaft is hollow with a hole diameter $d_0 > 0.4d$, the shaft diameter should be corrected according to the following formula:

$$d_c = d * \sqrt[3]{\frac{1}{1 - \left(\frac{d_0}{d_a}\right)^4}}$$

where d_a is the actual outside diameter of the shaft.

Intermediate shafts, tail shafts, and propeller shafts in ship shaft system are generally forged from high-quality carbon steel. Shaft couplings should also be forged from high-quality carbon steel. In some cases they can also be made of ductile iron.

The torque transmitted by the shaft system can be calculated based on the power it transmits and the shaft rotation speed:

$$M = \frac{9550P}{n}$$

in which M is the shaft transmission torque (N • mm), P is the shaft transmission power (kW), and n is shaft speed (r/min).

The thrust transmitted by the shaft system can be calculated based on the propeller power absorbed, propeller efficiency, and ship speed:

$$T = 1.94 \times \frac{P_p}{v} \times \eta_p$$

where T is the thrust transmitted by the shaft system (kN), P_p is the propeller power absorbed

(kW), v is ship speed (kn), and η_p is the propeller efficiency (CSSC 1999).

Propeller Design

The propeller consists of a boss with several blades of helicoidal form attached to it. It screws through the water in much the same way as a bolt screws through its nut and thus converts the engine torque into a direct thrust to push the ship ahead. The thrust is transmitted along the shafting to the thrust block and finally to the ship structure (Li 2013).

A propeller which turns clockwise when viewed from aft is considered right-handed, and most single screw ships have right-handed propellers. A twin screw ship will usually have a right-handed starboard propeller and a left-handed port propeller.

A solid fixed pitch propeller is an ordinary one. Although usually described as fixed pitch, the pitch does vary with increasing radius from the boss. The pitch at any point is however fixed, and for calculation purposes, a mean or average value is used (Li 2013).

A controllable pitch propeller is made up of a boss with separate blades mounted into it. An internal mechanism enables the blades to be moved simultaneously through an arc to change the pitch angle and the pitch (Li 2013).

The Match of Ship, Engine, and Propeller

When a diesel engine is used as a ship's main engine, the diesel engine will work with a propeller. For a given diesel engine, an appropriate propeller must be fitted. Correct match between the diesel engine and the propeller should not only make full use of the diesel engine power but also make this power in the allowable range within the entire operating speed range of the engine. In this way, the diesel engine can fully utilize, and at the same time, high economic efficiency, reliability, long service life, and low vibration of the engine can be obtained (Lv 2014).

Auxiliary Machinery Design

Ship's auxiliary machinery and its associated piping system are very complex. For different types of ships, their auxiliary machinery can be

arranged and designed with flexibility. The following are the basic principles to be followed in the design of all marine auxiliary machinery:

1. The weight of auxiliary machinery arranged on the left and right sides of the engine room should be kept as balanced as possible. At the same time, in order to increase the stability of the ship, the arrangement of auxiliary machinery should try to lower the height of the center of gravity of the ship.
2. The layout of the auxiliary machinery should enable the crews to manage, check, and maintain the equipment easily, and reasonable personnel access and maintenance space should be taken into consideration by designers.
3. The layout of the auxiliary machinery should reduce the space occupied by the engine room as much as possible to increase the ship's loading capacity and reduce the cost of shipbuilding.
4. Various safety measures should be fully considered, especially the safety of marine engineers.
5. The relative positions of various auxiliary machinery should be reasonable and do not interfere with each other during normal operation.
6. Ship's auxiliary machinery should ensure reliability and continuous operation of the main propulsion devices (CSSC 1999).

Key Applications

The following example explains the main principles in matching a MAN diesel engine with an appropriate propeller (Refer to www.mandieselturbo.com).

Propulsion and Engine Running Points

For a fixed pitch propeller, the relation between power and propeller speed is:

$$P = c * n^3$$

in which P = engine power for propulsion, n = propeller speed, and c = constant. Normally, estimates of the necessary propeller power and speed are based on theoretical calculations and

Ship Machinery Design,
Fig. 3 Ship propulsion
 running points and engine
 layout

experimental tank tests with assuming optimum operating conditions. The combination of speed and power obtained may be called the ship's propeller design point (PD), placed on the light running propeller curve 6 (Fig. 3). Some shipyards and propeller manufacturers sometimes use a propeller design point (PD) that incorporates all or part of the so-called sea margin described below.

The notations in Fig. 3 are defined as follows:

- Line 2: Propulsion curve, fouled hull, and heavy weather (heavy running), recommended for engine layout
- Line 6: Propulsion curve, clean hull, and calm weather (light running), for propeller layout
- MP: Specified MCR for propulsion
- SP: Continuous service rating for propulsion
- PD: Propeller design point
- HR: Heavy running
- LR: Light running

When the ship has sailed for some time, the hull and propeller become fouled, and the hull's resistance will increase. Consequently, the ship's speed will be reduced unless the engine delivers more power to the propeller, i.e., the propeller will be further loaded and will be heavy running (HR).

As modern vessels with a relatively high service speed are prepared with very smooth

propeller and hull surfaces, the gradual fouling after sea trial will increase the hull's resistance and make the propeller heavier running.

When the weather is bad, the ship's resistance may increase compared to operating in calm weather conditions. When determining the necessary engine power, it is a normal practice to add an extra power margin, the so-called sea margin, which is traditionally about 15% of the propeller design (PD) power.

When determining the necessary engine layout speed that considers the influence of a heavy running propeller for operating at high extra ship resistance, it is (compared to line 6) recommended to choose a heavier propeller (line 2). The propeller curve for clean hull and calm weather is line 6 representing a "light running" (LR) propeller.

Compared to the heavy engine layout line 2, we recommend using a light running of 3.0–7.0% for design of the propeller.

Besides the sea margin, a so-called engine margin of some 10% or 15% is frequently added. The corresponding point is called the "specified MCR for propulsion" (MP) and refers to the fact that the power for point SP is 10% or 15% lower than that for point MP.

Point MP is identical to the engine's specified MCR point (M) unless a main engine driven shaft generator is installed. In such a case, the extra

power demand of the shaft generator must also be considered.

The constant ship speed lines α are shown at the top of the figure. They indicate that the power required at various propeller speeds keep the same ship speed. It is assumed that the optimum propeller diameter is used for each ship speed.

Propeller Diameter and Pitch, Influence on the Optimum Propeller Speed

In general, the larger the propeller diameter D is, the lower optimum propeller speed will be obtained. The kW required for a certain design draught and ship speed can be seen as curve D in the figure below.

The maximum possible propeller diameter depends on the given design draught of the ship and the clearance needed between the propeller and the aft body hull and the keel.

The example shown in Fig. 4 is an 80,000 dwt crude oil tank with a design draught of 12.2 m and a design speed of 14.5 knots.

When the optimum propeller diameter D is increased from 6.6 to 7.2 m, the power demand is reduced from about 9,290 to 8,820 kW, and the optimum propeller speed is reduced from 120 to

100 r/min, corresponding to the constant ship speed coefficient $\alpha = 0.28$.

Once an optimum propeller diameter of maximum 7.2 m has been chosen, the corresponding optimum pitch in this point is given for the design speed of 14.5 knots, i.e., $P/D = 0.70$.

However, if the optimum propeller speed of 100 r/min does not suit the preferred/selected main engine speed, a change of pitch away from optimum will only cause a relatively small extra power demand, as shown in Fig. 4, keeping the same maximum propeller diameter:

- (Case 1) Going from 100 to 110 r/min ($P/D = 0.62$) requires 8,900 kW, i.e., an extra power demand of 80 kW.
- (Case 2) Going from 100 to 91 r/min ($P/D = 0.81$) requires 8,900 kW, i.e., an extra power demand of 80 kW.

In both cases the extra power demand is only of 0.9%, and the corresponding “equal speed curves” are $\alpha = +0.1$ and $\alpha = -0.1$, respectively, so there is a certain interval of propeller speeds in which the “power penalty” is very limited (MAN B&W Germany Ltd 2010).

Definition

The shipping navigation system is utilized to assist with the ship navigation; it helps to access precise data about ship performance and surrounding environmental information which may be critical for safe navigation. With the continuous development of marine technology, there are several navigation systems commonly used in ships, such as inertial navigation system, radio navigation system, integrated navigation systems, etc.

Inertial Navigation System

An inertial navigation system (INS) is a self-contained reference system based on inertial measurement provided by accelerometers and gyroscopes (IMO 2007), which used to estimate precise position, velocity, heading, pitch, and roll of a moving ship without the need for external references by applying Newton's mechanics laws in dead-reckoning process. This kind of navigation system is not only used in ship but aircraft, submarine as well.

An example of the inertial navigation system is shown in Fig. 1. The basic components of such a system include a computer, servo systems, core instruments – accelerometers and gyroscopes – and other motion-sensing devices. The initial position, heading, velocity, etc. are set into the

Ship Navigation System, Fig. 1 An example of the inertial navigation system

system from another source of human operator or GPS (Global Positioning System) satellite receiver and thereafter compute the updated position and velocity by processing information received from the motion sensors. Accelerometers detect and measure linear acceleration along the axis in which they lie. For constructing a triaxial inertial platform, three accelerometers are needed, one in each of three perpendicular planes: north-south; east-west; and vertical. Any movement of ships in any plane is continuously sensed by these accelerometers, and the output is sent to the computer to be integrated over time, by which the velocity can be calculated. Then the distance from departure can be worked out by integrating the velocity calculated; thus the actual ship position can be found. Three gyroscopes or a three-degree-of-freedom gyrocompass are maintained to measure rotational motion. Whatever rotational motion happens, the computer generates a torque signal to return this three-gyro-stabilized platform to horizontal position. Therefore, any roll, pitch, and yaw can be sensed, since it is always in the horizontal position and the angle between it and the ship can be used to judge roll, pitch, or heading. Each gyro output signal is amplified through the amplifier to operate servo system motor, which in turn keep the platform stabilized parallel to the earth surface and in the same direction.

As mentioned before, the inertial navigation system is entirely self-contained which means

once the initial information is set, it does not require outside information and radiate energy (IMO 1998). Thus, it shows the security advantage over other types of navigation systems such as radio navigation system for it cannot be detected. Also, it is able to be operated under harsh weather conditions, and data provided has high accuracy. However, the inertial navigation system still has several constraints. Firstly, since INS contains many precision mechanical parts, the entire cost is high. Secondly, it is noteworthy that initial alignment is always necessary which would cost much time. Lastly, the biggest disadvantage is integration drift. Specifically, the errors generated from the measurement of acceleration would gradually become bigger during integration procedure. Due to the new position needs to be calculated from the previous calculated one, the errors will accumulate with time, although these accumulating error characteristics are able to be known and modelled quite well. Therefore, these errors can be fixed from some other types of navigation systems such as satellite navigation system.

Radio Navigation System

The radio navigation system can be used to detect ship's position and guide the ship to sail along the scheduled route using radio technology. Radio waves can travel through the uniform medium in the straight line with the constant speed or be reflected by interface of two different mediums, which is the basic theory about how the system works. According to the propagation characteristics of radio waves, radio wave parameters including frequency, amplitude, propagation time, and phase launched by radio stations can be obtained by ships to calculate geometric parameters of the ship relative to radio stations such as distance and direction, which realizes the function of position and navigation. Since radio waves can travel very long distances, it makes a particularly good navigation system for ships. The common radio systems used worldwide for ships are radio direction finder, OMEGA and LORAN. However, they are too old to be used by modern ships. Thus, radar

navigation system and satellite navigation system have been developed and widely used by current ships.

Radar Navigation System

Radar navigation system is a type of radio navigation using radar for detection and ranging. Shipborne radars are electronic equipment which can use a rotating antenna to produce pulses of high-frequency electromagnetic waves around the water surface surrounding the ship to the horizon, listening for the waves reflected from objects to detect targets and thence displaying a picture of the ship's surroundings on a screen with cathode-ray tube (picture tube). The beam sent by the transmitter is narrow in the horizontal plane but wide in the vertical plane, which would make more objects caught when ship rolls. The shipborne radar can be classified under the X-band (9320–9500 MHz) or S-band (3000–3247 MHz) frequencies. If the size of antenna is constant, the X-band, being of higher frequency, is used for a crisper image and better resolution which reveals advantages in close-range detect, while the S-band is used especially when in rain or fog as well as for long-range detect since the higher sensitivity. Generally, ship with large size will be fitted with both X- and S-band radars, whereas smaller one will only take the X-band radar (Ludeno et al. 2013). A radar antenna mounted on a ship is generally on the high place, ensuring better transmitting and receiving ability. The strength of echo is related to the reflectivity of the surface of the reflecting object and the distance the waves travel. In most situations, the echo strength reflected from water is quite weak unless sea condition is very rough, while there will be strong reflection from ships, cliffs, and offshore constructions. By using radars, the mariners are able to maneuver ships irrespective of visible conditions, and it is, therefore, safe for ships to navigate even in thick fog.

The radar display screen is a vital part of the system, while a typical screen display is shown in Fig. 2. On the screen, ship position is located in the center. The scanning line is a radial straight

Ship Navigation System, Fig. 2 An example of the radar navigation system screen display

line drawn from the center outward, rotating synchronously with the transmitter. When electromagnetic waves that bounced off objects return to receiver, the image on the picture tube brightens (Ma et al. 2015). The positions of any reflecting objects can be seen on the screen, allowing the mariners to analyze the situation from the image.

In marine navigation, the most crucial function of the radar navigation system is avoiding collision, and with the evolution of technology, the ARPA (automatic radar plotting aid) has been used on today's ships. ARPA's introduction results from rapid advances in computer technology which can improve the conventional radar system. Plotting the targets also can be processed automatically instead of convention radar's manual plotting, tracking targets' bearing, speed, and closest point of approach (CPA), thereby calculating time of closest point of approach (TCPA). If the targets are under risk of collision or are navigating in a risky manner, dangerous alarms will be given to operators to avoid collision with ships or other offshore constructions. This intelligent system can alleviate workload of the ship's officers on the bridge.

However, radar and ARPA have limitations which influence their reliability. Radar sometimes may fail to detect small boats, floating ice, or other objects. Blind or shadow sector of the radar is caused by obstructions near the antenna such as masts and other structure or objects on the ship. Bearing discrimination usually happens when

radars need to distinguish between two small targets of same range but slightly different bearings, and they may be reported as the same. False echoes such as double echoes and multiple echoes are always existed resulting in detection errors.

Satellite Navigation System

The satellite navigation system is a particular type of radio navigation system. Unlike conventional ground-based radio navigation, the radio stations are moved to satellites on the ultimate high ground of space. Without concern about limitation of effective range, they are able to be “visible” from anywhere on Earth, so-called global navigation satellite system (GNSS). Such wide spatial converge is the most significant advantage of satellite navigation system among others. There are four main GNSS systems operating: the United States’ Global Positioning System (GPS), Russia’s Global Orbiting Navigation Satellite System (GLONASS), European Union’s Galileo, and China’s BeiDou Navigation Satellite System (BDS). Among them, GPS is the most used satellite navigation system worldwide.

The satellite-based navigation system can be used to calculate ship’s position by integrating information from a network of satellites. Every satellite involved in satellite network emits coded signals at precise intervals to receivers equipped on ships, and then receivers decode the signal information into position, distance between user satellite, and time estimates. This information can be utilized to measure the accurate transmitting satellite’s position and the distance between it and the receiver (production of the transmission delay time and speed of light). Calculating signal times of arrival from four or more satellites enables the receiver to determine its position.

In addition to position, the satellite navigation system can also plan a route for ships. The system is able to store thousands of waypoints. When choosing a waypoint, the distance from the current position, the bearing, as well as the time needed to arrive it at present speed can automatically be obtained. The hydrographic information and coastal features of the waypoints can be easily

found which can be the reference of waypoints selection.

The satellite navigation system has better accuracy and wider converge than previous land-based radio navigation system. Because of these advantages, the satellite navigation system has become the most mainstream navigation system in marine navigation, although it still has disadvantages. The operation of the satellite navigation system entirely relies on receiving satellite signals by radio, which means noise and interference may result in the failure. Moreover, sometimes satellite signals may not be precise owing to extreme atmospheric conditions such as geomagnetic storms.

Automatic Identification System

The automatic identification system (AIS) is a navigation system using shipborne transponders which operate in the VHF mobile maritime band to transmit information about the ship to other ships and to coastal base station automatically, contributing to reduce the risk of ship collisions and bolster the security of ports (Habtemariam et al. 2015). As a kind of self-reporting system, the data provided by AIS consists of both static data such as ship name, call sign, registration number, MMSI (Maritime Mobile Service Identity), and dynamic data such as position, heading, and speed, which can be learned on a display screen, all on a real-time, utterly automated basis. In addition to help masters to know about information of ships in the vicinity, AIS also can be used by maritime authorities to identify, locate, and monitor ships. The information of position, heading, and speed is mainly derived from GPS, while other information broadcast by the AIS is from shipboard electronic equipment and sensors, and all information is able to be uploaded automatically. According to the rules from IMO, AIS is mandatory for ships of 300 gross tons and upwards in international navigation and 500 tons and upwards for cargoes not in international waters and all passenger ships. A typical example of AIS is shown in Fig. 3.

Ship Navigation System, Fig. 3 An example of the automatic identification system

The AIS coverage range basically is dependent on the height of the antenna of both ships and base stations, and this range is limited to VHF range, around 20 nautical miles. To fix the problem, recently, it has become possible to receive AIS information by satellite in low earth orbit which are equipped with receivers. Such satellite-based AIS is enabled to monitor the location of all AIS-equipped ships in the most remote areas that may be beyond the reach of terrestrial-only AIS systems.

As a navigation aid, AIS is widely applied in collision avoidance and ship surveillance. For collision avoidance, AIS can track and monitor targets, while CPA and TCPA can be calculated automatically based on information of ships' movements, and alarms will be sent out if ships may encounter potential hazard. The system can improve situational awareness and be vital for navigators' decision-making process of collision avoidance (Perera and Soares Guedes 2015). As a surveillance tool, AIS enables shore side authorities to detect specific ships and their movements of vessels through the area. Shore side stations can also use the AIS channels to transmit current information on tides and locate weather conditions.

However, AIS still has several limitations. Firstly, since the information received by AIS is from other external sensors, thus the precision of AIS information depends on the accuracy of other

sensors. Secondly, not all ships have fitted with AIS, and the AIS transponder could be intentionally turned off. Thirdly, security of the ships will be challenged if the information transmitted is used illegally, especially in areas where piracy is rife.

Integrated Navigation System and Bridge System

As advances in sensor technology, diverse systems are being developed independently. However, due to the rapid development of modern marine technology, ships tend to be huge-sized, high speed, and professional, thereby single navigation system is unable to meet the needs of current navigation. The integrated navigation system (INS) is the combination of several navigation systems, using computer technology to integrate the data and information from various systems (IMO 1998). Generally, the INS consists of radar/ARPA, ECDIS, GPS, AIS, conning, gyrocompasses, antennas, and other sensors, by which the information of uninterrupted position, speed, heading, and further navigation safety data can be obtained. The system also contains capability of generating alarms and indications when the ship is in proximity to dangers. The motivation of INS's introduction is to promote the ship navigation safety through supplying integrated and augmented information and functions to assist navigators in geographic, traffic, and environmental hazards avoidance.

ECDIS refers to Electronic Chart Display and Information System. The introduction of INS, at large content, owes to the advancement of ECDIS, which is also the core of the system. ECDIS is developed to displace conventional paper nautical chart, which is also the requirements from SOLAS, aiming to ease the mariner's workload and enhance the navigation safety. It possesses automatic capabilities of route planning, ship monitoring, and automatic ETA (estimated time of arrival) calculation with the input of other systems such as radar, GPS, depth sounders, and gyrocompasses. Two widely used types of ECDIS charts are raster chart and vector chart.

Raster charts are raster graphics charts which are generated by transmitting paper charts to digital image through an accurate, detailed scanning process. Raster charts, therefore, are the direct copy of paper charts. This kind of chart only grows larger or smaller as per the zooming, and while the chart is rotated, everything on the chart rotates. Vector charts generated by computers are graphic representations of databases, consisting of digitized data necessary for safe navigation, such as coastlines, bathymetry, buoys, etc. The navigation systems using vector charts can be programmed to send out warns of impending danger using those data and information. All of the same information that is available on a raster chart can be obtained on a vector chart, moreover, with some useful additional data. Thus, the usage of vector charts is preferable to raster charts. According to IMO (1998), raster charts are permitted to be used in the absence of vector charts.

The latest performance standards for INS are detailed in the IMO (2007) and apply to all newbuildings since 1st January 2011 where INS are fitted. The standards told that an INS is required to integrate the tasks of collision avoidance, ship monitoring, route monitoring, route planning, navigation control data status display, and a centralized human-machine interface for alert management on multifunctional displays. Moreover, alert management is one of the most critical parts of the INS, enhancing navigation safety. Every alert or abnormal condition is distinguished between the three priorities by the INS, on the basis of urgency, as an alarm, a warning, or a caution. Each of the three types is reported diversely to navigator by sending out visual and audible signals and displaying messages. Alarms which may represent highest urgency are usually must include danger of collision and grounding. ECDIS also provides a critical integration platform for multi-sensor fusion, which is significant for INS.

According to INS performance standards, INS can be classified into three categories, as INS(A), INS(B), and INS(C). INS(A) is required to at least provide information of ship position, speed, course, and time. Also, alarm signal needs to be emitted in the situation of any sensor failure. For

INS(B), in addition to possess functions of INS (A), it is required to provide relative information for hazard avoidance. This is done by marking information of position, speed, course, depth, and other potential hazards on ECDIS real time and autonomously. INS(C), which has functions of INS(B), need additionally implement automatic navigation control functions as well as ship performance monitoring.

Since the multisource data need to be integrated by INS, the information fusion technology reveals the significance for constructing this centralized fusion system. The information from various sources (homogeny, heterogenic) will be preprocessed, linked, and refined and subsequently obtain a newly higher quality. For instance, AIS and radar navigation system are two representative navigation systems with their own limitations, and these limitations can be made up by a level of information fusion. Presenting such integrated information from AIS and radar on ECDIS is of paramount importance for improving detection precise and reducing navigation risk. Generally, there are two main types of approaches to fuse information- decentralized and centralized approaches. For the former, sophisticated data is initially processed in each sensor and subsequently fused using a proper algorithm. For the latter, default data from each sensor, after a preprocess, is transmitted to a fusion center and then processed together also using the appropriate algorithm. The widely used algorithms for information fusion are weighted average method, Kalman filter, Bayesian estimation and neural network, etc.

Integrated bridge system (IBS) as shown in Fig. 4 is defined as a navigation management system which developed from integrated navigation system (INS). IBS can be considered as a combination of systems, which are interconnected to provide centralized access to navigational, control, propulsion, and monitoring information, aiming to enhance navigation safety and promote efficiency of ship navigational capabilities. For today's IBS technology, it may consist of autopilot, gyro, ECDIS, AIS, dynamic positioning system, power distribution system, meteorological instruments, conning display, and GMDSS

Ship Navigation System, Fig. 4 An example of the integrated bridge system

(Global Maritime Distress and Safety System), and all systems or instruments interact in a complete network which can be divided into two sub-networks, namely, navigation system and automation system. The navigation system is responsible for navigation safety, functioning like INS, while the automation system is in charge of power management and propulsion control as well as additional task such as bilge and ballast control, alarm, and monitoring systems. Conning displays of IBS can present navigation information such as ship position, speed, course, and rudder and propulsion data such as propeller situation, thruster, power, and states of wind and wave to operators and assist their decision-making.

Definition

Stricter environmental regulations on shipping, the maritime community is eagerly seeking for solutions to increase a ship's energy efficiency. Furthermore, the climate targets set up by authorities, such as in EU and some western countries, require that at least 10% of the transport fuels should come from renewable sources by 2020. This climate ambition triggered intensive research and innovation activities to promote auxiliary propulsion using renewable energy such as wind and waves and to develop energy efficiency measures. Any maritime-related research and development activities must rely on the correct description of Meteorological and Oceanographic (MetOcean) environment (wind, wave, etc.) that a marine structure may encounter. Therefore, large instruments, such as satellite, climate ocean models, buoys, and even expensive ship onboard measurement devices, are launched to measure the safety and energy performance of marine systems and their surrounding sea environments.

Weather conditions at sea vary in space and time resulting in variable environmental loads acting on ship structures. The load variability can cause material deterioration and may lead to mechanical/structural failures or breakdowns in extreme sea conditions. Thus, accurate models describing the variability of MetOcean conditions are essential for safe maritime operations. Statistics and probability theory are mathematical tools to derive useful models describing the variability of sea environments a ship encounters. Hierarchical models can be used to represent variability at different time scales, hours, days, seasons, and years, while in spatial scales ranging from a few to 1000 kilometers.

The detailed spatial-temporal environmental models for short- and long-term descriptions of the variation and correlation of sea environment give tools to generate the weather conditions for the whole service time of ship. These conditions can be used to estimate a ship's energy performance and efficiency for the design, validation, and implementation of energy efficiency measures in ships (such as wing sails, voyage optimization systems). Additionally, those models give

means to estimate risks for system failures and methods to calculate payback time of the energy efficient/harvest measures.

The Sea Surface Elevation and Wind Gusts

In the finest scale, environmental loads applied on ships and generated by waves and wind gusts are stationary and homogeneous. In order to estimate the loads, one needs dedicated software to evaluate responses of structures sea surface and wind pressure variability. The Gaussian distribution is often used to describe the sea surface and wind variability. (In shallow water locations or in extreme seas, nonlinear quadratic corrections are added to the Gaussian model.) The Gaussian models are very convenient since the stationary and homogenous sea surface and winds are then uniquely described by their average values and the power spectral densities (equivalently variances and correlations) (Lindgren 2013). Tools to find various load characteristics (wave-length, period amplitudes, etc.) are developed (Brodtkorb et al. 2000; Podgórski et al. 2000).

Several parametric models were proposed for the sea and wind spectra, e.g., Pierson Moskowitz, Jonswap sea spectra, and Davenport, Harris, and Kaimal spectra for gust wind variability. For example, the Pierson-Moskowitz spectrum is often used to model fully developed sea as by

$$S(\omega) = c\omega^{-5} \exp\left(-1.25\omega_p^4/\omega^4\right), \quad (1)$$

$$c = 0.3125H_s^2\omega_p^4, \quad \omega_p = 2\pi/T_p.$$

The important parameters describing an ocean wave spectrum are integral of the spectrum, i.e., signals variance equal to $H_s^2/16$ and the peak frequencies T_p (or wave number). For wind spectrum description, it is variance and an average wind speed W . Spectral parameters also called environmental parameters define sea conditions. Typical power spectral densities $S(\omega)$ and means m of sea surface elevation (wind speeds) define Gaussian models, which describe short-term variability of a sea surface and wind velocity in time

and/or space. For example, given a spectrum $S(\omega)$, a time series $X(t)$ can be generated using the spectral representation, viz.,

$$X(t) \approx m + \sum_i \sqrt{S(\omega_i) \Delta \omega} R_i \cos(\omega_i t + e_i),$$

where $\Delta \omega = \omega_{i+1} - \omega_i$; R_i , e_i are independent Rayleigh and uniformly distributed variables, respectively (see Brodtkorb et al. (2000) and Lindgren (2013) for more detailed presentation).

The spatiotemporal models can be used to describe environmental parameters H_s , T_p , and W in larger scales when the condition of stationarity and homogeneity of sea conditions cannot be assumed. Since the parameters changes relatively slowly, they could be modeled as correlated random variables. This section will introduce random models describing the variability of environmental parameters in geographical locations and with seasons, i.e., spatiotemporal models of $H_s(t, x, y)$ and $W(t, x, y)$ where t has units days and x degree of longitude, while y degrees of latitude. The parameter $T_p(t, x, y)$ is at present modeled conditionally on $H_s(t, x, y)$ values.

Spatiotemporal Local Models for Significant Wave Height H_s

The variability of H_s is described by means of probability distribution. In the literature, the

H_s distribution is typically understood as the long-term distribution of significant wave height at some location or region. The long-term distribution can be interpreted as variability of H_s at a randomly taken time during a year. Often Weibull distribution fits well to the data. Limiting time span to a specific time window such as January month will affect the H_s distribution, because the variability of H_s depends on season. By shrinking the time span to a single moment t and geographical region to a location (x, y) , the distribution of $H_s(t, x, y)$ one obtains can be obtained. This will be the meaning of spatiotemporal distribution of H_s as used in this section. According to the study in Baxevari et al. (2005), for time period limited

to couple of weeks and regions of about 4 degrees in diameter, the distribution of H_s is log-normal, i.e., $\ln H_s(t, x, y)$ is normal with mean $m(t, x, y)$ and variance $\sigma^2(x, y)$, in Mediterranean and central North Atlantic. At fixed position denoted by $\mathbf{p}$, the temporal variability of mean $m_p(t)$ was modeled by means of annual cycle

$$\begin{aligned} m_p(t) &= \beta_0 + \beta_1 \cos(\phi t) + \beta_2 \sin(\phi t) \\ \phi &= 2\pi/365.2 \end{aligned} \quad (2)$$

time measured in days, and parameters β all depend on geographical location $\mathbf{p}$. Furthermore, it is found in Baxevari et al. (2005) that locally, i.e., in a neighborhood of location $\mathbf{p}$, the spatial correlation between the logarithms of significant wave heights with positions (x, y) away could be sufficiently accurately described by means of

$$\rho_p(x, y) = \exp\left(-(x^2 + y^2)/2L_p^2\right),$$

where L_p called correlation length depends on geographical location of the small region and with month. The $\ln H_s(x, y)$ has a two-dimensional spectrum

$$S_p(\omega_1, \omega_2) = \frac{\sigma_p^2 L_p^2}{2\pi} e^{-L_p^2 \frac{\omega_1^2 + \omega_2^2}{2}},$$

and the local spatial field in a neighborhood of a geographical location $\mathbf{p}$ can be approximated by

$$\begin{aligned} X(x, y) &= \ln H_s(x, y) \\ &\approx \Delta \omega \sum_{ij} \sqrt{S_p(\omega_i, \omega_j)} R_{ij} \cos(x\omega_i + y\omega_j + e_{ij}), \end{aligned} \quad (3)$$

where $\Delta \omega = \omega_{i+1} - \omega_i$, R_{ij} , e_{ij} are independent Rayleigh and uniformly distributed variables, respectively.

Note that (x, y) are in equivalent degrees so that degree in both longitude and latitude stands for the same distance when measured in kilometers. Finally, spatial models for the variability of the significant wave height on the world oceans can be accessed in Baxevari et al. (2008a). An

Ship Operational Environment, Fig. 1 Estimates of median significant wave height in February (top plot) and August (middle plot) and estimates of variance of $\ln H_s$ (bottom plot). Note the variance is independent of a season

example of the median value is presented in Fig. 1. The parameters β and σ^2 and 12 correlation lengths L have been estimated at 1861 different 4×4 degree regions.

Local H_s Dynamics

The variability of significant wave height in time and space has been studied in Baxevani et al. (2008b), where a local spatiotemporal $X(t, x,$

$y) = \ln H_s(t, x, y)$ proposed. Following the work carried out by Baxevari et al. (2003) and Longuet-Higgins (1957), a median velocity (v_x, v_y) is modeled by a moving random Gaussian field. A first-order autoregressive model, AR(1), was used to model “memory” of the field, leading to the following spatiotemporal correlation function

$$\rho(t, x, y) = \exp\left(-\left((x - v_x t)^2 + (y - v_y t)^2\right)/2L^2\right) \exp(-\lambda|t|). \quad (4)$$

This type of spatial-temporal covariance has been originally used in Cox and Isham (1988) and Gupta and Waymire (1987) for modeling rainfall.

The velocity field (v_x, v_y) was estimated using ERA40 data set, while the parameter λ was estimated using time series of buoy H_s observations. This was done by fitting the temporal correlation

$$\begin{aligned} \rho(t, 0, 0) &= \exp(-t^2/2T^2) \exp(-\lambda|t|), T \\ &= L/\|\mathbf{v}\|, \end{aligned} \quad (5)$$

to observed autocorrelation in measured time series by buoys. Here $\|\mathbf{v}\| = \sqrt{v_x^2 + v_y^2}$. The spatiotemporal field $X(t, x, y)$ can be simulated in a recursive way. For any $t = i \, dt$, $i > 0$, $X(0, x, y) = X_0(x, y)$,

$$\begin{aligned} X(t, x, y) &= \rho X(t - dt, x - v_x dt, y - v_y dt) \\ &+ \sqrt{1 - \rho^2} X_i(x, y), \end{aligned} \quad (6)$$

where $X_i(x, y)$ is independent simulation of the spatial field $X(x, y)$ by Eq. (3). Here $\rho = \exp(-\lambda \, dt)$.

Global Model

In addition, the local spatiotemporal fields have been further generalized to the global non-homogeneous and nonstationary fields in Baxevari et al. (2008b). This involved evaluation of a flow φ defined by the velocity fields. Clearly, $\mathbf{p} = \varphi(\mathbf{q}, t, s)$ is the position at time s of the point, and at time t , the position moves to q . Having the

flow the recursion is easily adopted to a non-homogeneous case (Baxevari et al. 2008b).

The model has been simplified in Podgórski and Rychlik (2014) by approximating the local correlation (5) as follows:

$$\begin{aligned} \rho_{\mathbf{p}}(t, 0, 0) &\approx \exp(-t^2/2\tau^2), \\ \tau &= \pi\left(-\lambda T^2 + \sqrt{\lambda^2 T^4 + T^2}\right), \end{aligned} \quad (7)$$

The parameter τ depends on location $\mathbf{p}$ and season.

Then the local spatiotemporal correlation ρ (4) in a neighborhood of a location $\mathbf{p}$ can be written as follows:

$$\rho_{\mathbf{p}}(t, x, y) = \exp\left(-(t, x, y) \Sigma_{\mathbf{p}}(t, x, y)^T / 2\right), \quad (8)$$

where $\Sigma_{\mathbf{p}}$ is a positive definite matrix with elements depending on L, v_x, v_y , and τ . Now the covariance function between $\ln H_s$ at any locations on the oceans $\mathbf{p}$ and $\mathbf{q}$ is given by

$$\rho(\mathbf{p}, \mathbf{q}) = \sqrt{\frac{2^3 |\Sigma_{\mathbf{p}}|^{-1/2} |\Sigma_{\mathbf{q}}|^{-1/2}}{|\Sigma_{\mathbf{p}}^{-1} + \Sigma_{\mathbf{q}}^{-1}|}} e^{-\mathbf{z}(\Sigma_{\mathbf{p}}^{-1} + \Sigma_{\mathbf{q}}^{-1})^{-1} \mathbf{z}^T}, \quad (9)$$

where $\mathbf{z} = \mathbf{q} - \mathbf{p} = (t_{\mathbf{q}} - t_{\mathbf{p}}, x_{\mathbf{q}} - x_{\mathbf{p}}, t_{\mathbf{q}} - y_{\mathbf{p}})$ and $|\Sigma|$ is the determinant of Σ . Consequently for any collections of locations, $\mathbf{p}_i, i = 1, \dots, n$, $\ln H_s(\mathbf{p}_i)$ is a vector of Gaussian variables with means $m(\mathbf{p}_i)$, variances $\sigma_{\mathbf{p}_i^2}$, and correlations $\rho(\mathbf{p}_i, \mathbf{p}_j)$ as in Eqs. (2) and (9). Some further developments of the global model have been done in Ailliot et al. (2011).

Simulation of Encountered H_s

For a vessel moving with velocity $\mathbf{v}_{shp}$ as in Fig. 2, the local covariance between logarithms of encountered H_s is of the following form as in Eqs. (5), (6), and (7)

$$\rho(t) = e^{-\frac{|\mathbf{v}_{shp} - \mathbf{v}|^2 t^2}{2L^2}} e^{-\lambda|t|} \approx e^{-\frac{t^2}{2\tau^2}},$$

where

Ship Operational Environment, Fig. 2 Heading angle α of a ship

$$\tau = \left(-\lambda T_v^2 + \sqrt{\lambda^2 T_v^4 + T_v^2} \right), \quad (10)$$

$$T_v = L / \left\| \mathbf{v}_{shp} - \mathbf{v} \right\|.$$

In general, τ depends on route (season and position of vessel and speed computed from the route), which is a function of time t . The correlation between logarithms of encountered significant wave heights at time t, s $X(t), X(s)$ is given by (Podgórski and Rychlik 2014) as:

$$r(t, s) = \sigma(t)\sigma(s) \sqrt{\frac{2\tau(t)\tau(s)}{\tau(t)^2 + \tau(s)^2}} e^{-(t-s)^2 / (\tau(s)^2 + \tau(t)^2)}. \quad (11)$$

Below, the use of the proposed model is demonstrated to simulate the significant wave heights encountered along the route presented in the Fig. 3. The mean values $m(t)$ and $\sigma^2(t)$ are shown in Fig. 1. The average duration of encountered storm (in hours) $\tau(t)/\pi$ is given in Fig. 4. Here a storm duration is defined as time the encountered H_s stays above the median. One can see that the time duration of storms/calm periods on the route from Europa to America is about 40 h, while the sailing time is about 160 h. Thus one can expect to meet three storms on this route. On the other hand, the route from America to Europe took about 125 h, the average storm period is 130 h, and hence one can expect to meet one storm.

We turn now to more detailed description of the simulation algorithm. The inputs are functions $m(t)$, $\sigma^2(t)$, and $\tau(t)$ presented in Figs. 1

and 3. The functions are sampled with time step 0.5 h (the same as frequency of on board measured H_s). In the following, we denote by $\mathbf{t}, \mathbf{s}$ vectors of time points sampled with frequency two per hour along the route. Furthermore, the significant wave height observed at points $\mathbf{t}$ is denoted by $H_s(\mathbf{t})$, while their logarithms by $X(\mathbf{t})$ and the vector of their means by $m(\mathbf{t})$. The covariance matrix between $X(\mathbf{t}), X(\mathbf{s})$, with entries $r(t_i, s_j)$ computed using (11), is denoted by $r(\mathbf{t}, \mathbf{s})$. Using the introduced notation, the samples of $H_s(\mathbf{t})$ can be simulated as follows

$$H_s(\mathbf{t}) = \exp \left(m(\mathbf{t}) + \sqrt{r(\mathbf{t}, \mathbf{t})} \mathbf{Z} \right),$$

where $\mathbf{Z}$ is a vector of independent standard normal and $\sqrt{A}$ is any matrix such that $A = \sqrt{A}\sqrt{A}^T$.

For the ship routes presented in Fig. 3, three simulated H_s encountered along the route are compared with the measured H_s as in Fig. 5. The simulated values can well reflect the characteristics of the significant wave height measured along the ship routes. In the following subsection, we will show a solid example of using the model and simulation to estimate the ship's performance, i.e., damage accumulation, during the measured route. The estimated damage results will be compared with the full-scale measurement to validate the capability of the model for other similar maritime application.

Expected Fatigue Damage During a Voyage

In the maritime industry, safety and energy efficiency are two fundamental issues that have to be seriously taken into account in all maritime-related activities. For the evaluation of ship safety and energy consumption-related parameters, to get reliable sea conditions is one of the key elements in the evaluation process. For example, estimation of expected fatigue $\mathcal{D}_\beta$ for a specific trade route is a central issue in the reliability analysis to ensure a ship's structural integrity. A common approach is to represent encountered loads as a sequence of stationary sea states during which the expected damage increases at a rate

Ship Operational Environment, Fig. 3 Estimates of the median H_s velocity (v_x , v_y) for the wave fields in February (top) and August (middle). The lengths of vectors are not up to scale. Bottom: estimates of the median velocity (v_x , v_y) along the route in January

Ship Operational Environment, Fig. 4 Parameters of $X(t) = \ln H_s(t, \mathbf{p}(t))$ for the route presented in Fig. 3 (bottom). Left: the expected duration τ / π of encountered storm. Right: covariance Eq. (11) between $X(t)$ and $X(s)$. The covariance is zero for $160 < t < 270$ or $160 < s < 270$ since the vessel is close to or in the harbor

Ship Operational Environment, Fig. 5 Three simulated H_s encountered along the route presented in Fig. 3. The simulated values are exhibited in solid lines, while dots represent measured H_s on board of a vessel sailing the same route

depending on shipping conditions and sea states parameters. The damage accumulation rate at time t is denoted by $d(t)$.

The method introduced in Mao et al. (2010) is illustrated for a container ship traveling regularly between Europe and North America. The fatigue

damage rate $d(t) = d$ in a container ship was given, viz.,

$$d = \frac{0.47C^\beta}{a} \times \left(\frac{H_s^{\beta-1/2}}{3.75} - \frac{2\pi}{g} \frac{H_s^{\beta-1}}{3.75^2} \|\mathbf{v}_{sh}\| \cos \alpha \right) = d(H_s, \mathbf{v}_{sh}, \alpha), \quad (12)$$

where H_s is significant wave height encountered by the ship, $\mathbf{v}_{sh}$ is her velocity, and α is the heading angle as given in Fig. 2 or by using the velocity of $\mathbf{v}$ of H_s field through $\cos \alpha = \frac{\langle \mathbf{v}_{sh}, \mathbf{v} \rangle}{\|\mathbf{v}_{sh}\| \|\mathbf{v}\|}$, where $\langle \cdot, \cdot \rangle$ is the inner product between vectors. For compactness of the formulation, the dependence on time t and a position of the ship $\mathbf{p}(t) = (x(t), y(t))$ (a route of the ship) is not explicitly shown. In the formula a is fatigue strength of material taken from S-N curve of parameters $a = 10^{12.76}$ while $\beta = 3$. The constant C depends on the type of a ship and the geometry of ship detail: ship speed and heading angle. It can be evaluated using linear strip code, beam theory, and stress concentration factor, here $C = 20$. It is also assumed that actual encountered waves travel in the same direction as that the field H_s moves in.

The method is constructive and requires a detailed shipping plan which consists of voyages between harbors. A single voyage is then represented by a route, i.e., a sequence of times t_i (in hours) of the (approximately) constant sea states and corresponding positions in space $\mathbf{p}_i = \mathbf{p}(t_i)$ (in degrees). In Fig. 3, *bottom*, a route that will be considered in examples is presented as a black line. The route started close to England and took 408 h to sail (time in an American harbor included).

Now for a given route which sails in T hours the accumulated damage is

$$\mathcal{D} = \int_0^T d(t) dt \approx \sum d(t_i) \Delta t, \quad (13)$$

and the expected damage $E[\mathcal{D}] \approx \sum E[d(t_i)] \Delta t$ is used to estimate risk for cracking of ships details.

Here expectation $E[d(t_i)]$ averages the variability of significant wave heights, heading angle, and the ship velocity at time t_i when ship is at position $\mathbf{p}(t_i)$. In order to find the distribution for any route, one needs atlases of distributions of $H_s(\mathbf{p})$ at any position and season (here represented by a month). Several such atlases exist, and an example of such maps is presented in Fig. 1 one estimated from H_s recorded by satellites.

The second problem is description of variability of the ship velocity $\mathbf{v}_{sh}$ and heading angle α . Here the ship's velocity and heading along the route are approximated by their average values that are derived as follows. The speed is taken as the "design speed," and the direction is evaluated as the tangent to the route. The heading is taken as the angle between the average ship velocity and the median velocity of H_s at the position as shown in Fig. 3.

Here we shall illustrate the presented methods by estimating the expected damage accumulation rate along the route presented in Fig. 3 (*bottom*) that took 17 days to sail in January month. The damage rate is given by Eq. (12) with ship velocity and H_s field velocity replaced by their median values (see Podgórski and Rychlik (2014) for more details). The average H_s field velocities along the route are available and presented in Fig. 3. What remains is computations of expectations of H_s^2 and $H_s^{2.5}$. For log-normally distributed H_s defined by $m = E[\ln H_s]$ and $\sigma^2 = \text{Var}(\ln H_s)$, the average value of H_s^r is given by

$$E[H_s^r] = \exp(rm + r^2\sigma^2/2).$$

Since the duration of the voyage is less than 1 month, the dependence of distribution of H_s on time can be neglected, and hence the damage rate can be computed when the parameter values $m(\mathbf{p})$ and $\sigma^2(\mathbf{p})$ are known for locations $\mathbf{p}$ along the route. This can be done using the model proposed in Baxevari et al. (2005) and fitted to all locations on oceans in Baxevari et al. (2008a). Typical fits following this approach see Fig. 1.

Using the evaluated damage rates presented in Fig. 6, the accumulated damage for the entire voyage can be computed. The average damage

rate (dashed line) results in expectation that 0.99% of the total fatigue life has been “consumed” in this 17 days long voyage. This estimate applies to a midship location in 2800 TEU container ship (see Mao et al. (2010) for more details). During six winter months, between 6 and 8 such voyages can be undertaken which indicates high risk for cracking in some ship details before the design life of 20 years.

The observed damage rates, although uncertain due to large estimation errors and missing values, give accumulation of 0.72% of the life during the voyage. The difference between observed and the expected damage is caused not only by randomness of the sea conditions but also by captain decisions and routing programs. A wish to avoid predicted large storms resulted in the decision of taking longer route to the south to avoid the worse sea conditions, but despite these precautions, still three storms have been met on route to America.

Since on the route back to Europe one is sailing in similar direction as the motion of storms, the damage rate is much smaller. The weather in the middle of this route is harsher than the conditions that can be met on the chosen route to America as seen from the parameters m and σ^2 in Fig. 6 (left). Mathematically, it is the term $\|\mathbf{v}_{sh}\| \cos \alpha$ that

makes the damage rate smaller, and as a result, 80% damage were accumulated on the way to America and only 20% on the way back. The difference is a well-known fact, and hence sailing from America to Europe is often taken along the shortest route with a maximum speed.

Spatiotemporal Models for Winds

There are tremendous renewable wind powers in the open sea. For the development of auxiliary propulsion, using wind power in ships relies on accurate description of wind conditions along a ship’s actual sailing route. In such application, the wind conditions often relate to the variation of wind speeds encountered by ships. A good way to model the variation is by developing some statistical spatiotemporal wind models. Development of a fully spatial-temporal model to describe the variation of wind velocity seems to be a difficult problem (see Monbet et al. (2007) for a review). A simpler way is to derive conditional distributions of wind direction given the wind speed. In Bessac (2014), statistical means to derive the conditional distribution close to French coast in January month are given. The

Ship Operational Environment, Fig. 6 Analyses for the route in Fig. 3 (bottom) in dependence on sailing time. Left: mean (top) and variance (bottom) of $\ln H_s(t)$.

Right: the expected (mean) damage rate (dashed line) vs. the observed damage rate (solid line)

spatiotemporal model for wind velocity was discussed in Bessac et al. (2016a, b). The approach used hidden Markov processes to model properties of wind velocity on a grid. This is numerically a very intense method, which limits the size of the grid.

Furthermore, the average wind speed is an important parameter in wind gust spectra and models for wind speed variation in both space and time. The spatiotemporal models for wind speeds in North Atlantic and Arctic have been proposed in Rychlik and Mao (2014), Rychlik (2015), and Mao and Rychlik (2018). The proposed models are of the same type as used to describe variability of the significant wave heights. The main difference is that the logarithmic transformation of data is replaced by an exponential transformation proposed in Brown et al. (1984). In Mao and Rychlik (2016), it was also demonstrated that wind speeds encountered by a ship are Weibull distributed. In this work it was also demonstrated that in the Caribbean Sea, the Weibull model does not fit well with the observed data in regions where extreme wind speeds can arise during hurricanes or tropical storms. Rarity of such events makes it difficult to find a suitable transformation so that transformed wind speeds can be model as Gaussian fields, i.e., the model used to describe the variability of significant wave heights.

In Rychlik and Mao (2018), a new model for exponentially transformed wind speeds was proposed. It is a sum of a Gaussian field and several non-Gaussian random fields (with Laplace distributed amplitudes), which are independent and randomly spread in time and space. These non-Gaussian fields describe strength and dynamics of cyclones and tropical storms. In Rychlik and Mao (2018), only local model, valid in geographical region of about 4 degrees radius and for a period of 1 month, was presented. A global model is not developed yet. Work in this direction is undertaken. Furthermore there is no spatiotemporal model for wind speeds over oceans estimated yet. Consequently modeling of spatiotemporal wind speed variability is less developed as the modeling of significant wave heights.

Ship general design

Definition

Ship design can be, by discipline, subdivided into overall design, structural design, outfitting design, machinery design, and electric design, wherein the overall design has been recognized to play a dominant role over others. Figure 1 shows the ties among each discipline.

Ship overall design is a process that starts from the determination of ship's main dimensions and generation of hull form, followed by general arrangement and lightweight estimation, based on which the ship's performances such as velocity, maneuverability, sea-worthiness, and stability can be further analyzed. The coverage of ship overall design ranges from model tank testing to delivery of the as-built document, so to speak.

Scientific Fundamentals

Basic Theory

As the fundamental theory and method of ship overall design, the knowledge contained in the

Ship Overall Design, Fig. 1 Status of overall design

following three subjects have to be learned and mastered.

Ship hydrostatics mainly introduces how to generate ship lines and calculate hydrostatic data, floatability (static equilibrium of a ship), initial stability (at a small rolling angle), large angle stability, and launching process.

Ship dynamics based on fluid dynamics elaborates on the basic principle of ship resistance, propulsion, maneuverability, and sea-keeping performance.

Principles of ship design, developed on the ground of above fundamental theory, teach people how to determine the ship's main dimensions, general arrangement, lightweight, capacity, cost, and the like.

Input of Design

Ship overall design has to proceed in accordance with following requirements.

Mission and owner's requirements addressed in contract and ship specification such as cargo category and capacity, principal characteristics, rules and regulations, number of crew, endurance, service speed, specific fuel oil consumption (SFOC), deadweight, as well as the vessel design life.

Classification requirements reflected in rules issued by certain classification Society such as American Bureau of Shipping (ABS) or China Classification Society (CCS) which mission is to provide a ship classification service and supervision over the design quality and shipbuilding process.

Regulatory requirements stipulated in all the documents such as conventions, Clcodes, and resolutions issued by the International Maritime Organization (IMO). The most important two conventions, among those documents, are the International Convention for the Safety of Life at Sea (SOLAS) and the International Convention for Prevention of Pollution from Ships (MARPOL). The former is mainly concerned about the safety of human life onboard, while the latter is much concentrated on the prevention of various pollutions from ships.

ILO Convention No. 92 & 133 published by the International Labor Organization (ILO). The

articles in this convention are mainly about screw's living conditions to be satisfied during the overall design.

Regulations of authorities issued by, for example, USCG (United States Coast Guard) or ACP (Autoridad Del Canal De Panama), etc. For ships intent to go through US waters or Panama Canal, those regulations have to be followed up.

Design Approach

"Design Spiral": An Iterative Method

The design spiral shown in Fig. 2 effectively illustrates the sequential course of ship design through the various design steps, the repeating, iterative procedure for the determination of ship dimensions and of other properties, and, finally, the gradual approach to the final stage of detailed ship design.

The usual and recommended steps when the preliminary ship design is elaborated are listed below:

- (a) Critical evaluation of ship buyer's major requirements with emphasis on those which influence the main dimensions' selection.
- (b) Data gathering (by ship type, size, DWT, speed, and power of main engine installed onboard) of built similar ships in available publications, including databases. Designers working in the shipbuilding industry or design offices may exploit available technical information about built ships filed in the design department's records.
- (c) Identification and study of the relative/ corresponding regulations concerning the specific ship type design, construction, and operation: conventions, national and international regulations, class society rules, technical notes, guidelines, and instructions.

"Parent (Basic) Vessel": A Transformation Method

With accumulation of ship design and development, a ship form database composed of variety of excellent ship types has been formed, which can be used as a reference for subsequent ship design. An excellent ship data from such database can be

Ship Overall Design, Fig. 2 Design spiral

chosen as a parent ship for a new ship design, provided both vessels are similar in size and type. This can get rid of a tedious and time-consuming spiral design process and ensure that the new ship is free of risk in performance and safety. Such a result can be concluded even at the very beginning of ship design without detailed calculation. The parent vessel design method is widely recognized and accepted as the first choice for modern ship design.

Key Applications

As a results of key application of above fundamental theory and design approach into ship overall design, some documents (output of ship overall design) would be worked out as shown, taking a document list for typical oil tanker as an example, in Table. 1.

Further interpretations to parts of such documents are given as following.

Lines

An important drawing used to describe the shape of a ship (shown in Fig. 3). It gives an offsets table and three orthogonal views, the so-called buttock, body, and waterline which worked out from the Offsets. The main dimensions and ship form coefficients are also included in this plan. Lines is considered the basis of all the ship performance calculation as well as an indispensable shape reference for general arrangement and structural design.

General Arrangement

A drawing presenting the overall appearance of the ship consisting of profile view, deck/platform views, and front view (see Fig. 4). It divides the whole ship into several functional zones such as

Ship Overall Design, Table 1 Documents produced in ship overall design

cargo holds, machinery space, fore, and aft parts as well as accommodation zone. Cabins layout on decks in accommodation zone, equipment layout

on platforms in machinery space, subdivision of liquid tanks and cargo holds, layout of mooring equipment on the fore and aft deck, all the

Ship Overall Design, Fig. 4 General arrangement

hatch, stairway and passageway, positions of navigation, and life-saving and communication apparatus are given as a foundation for future development.

In addition, the main particulars of the ship, such as main dimensions, displacement, deadweight, main engine power, main engine revolution, complement (number of crew), endurance, deck height, and classification notation, are also indicated in this drawing.

Hydrostatic Data

A set of hydrostatic data that varies against draft. Usually the following parameters have to be included:

- Molded displacement of volume: V .
- Displacement: D .
- Water plane area: A_w .
- Tons per centimeter immersion: TPC.
- Longitudinal center of floatation: LCF.
- Longitudinal center of buoyancy: LCB.
- Vertical center of buoyancy: VCB.
- Transverse metacenter: KM_T .
- Longitudinal metacenter: KM_L .
- Wet surface area: A_S .
- Moment to change trim 1 cm: MTC.
- Midship area coefficient: C_M .
- Waterplane coefficient: C_W .
- Block coefficient: C_B .
- Prismatic coefficient: C_P .

Capacity Data

A document showing capacity data of all the cargo holds and liquid tanks which would offer necessary data for inclining test, stability calculation and calculation for various loading condition, and so forth.

The data would include cargo hold and liquid tanks capacity, centroid position and free surface inertia moment of each cargo hold, and liquid tank at different load height.

Capacity Plan

A plan presenting the size and position of all the cargo holds and liquid tank of the vessel.

A summary information including category, position, capacity, centroid position, and maximum free liquid surface inertia moment for each cargo hold and liquid tank would be given in this plan.

Tank Sounding Table

A document showing all the liquid volume in tank corresponding liquid depth, offering necessary data for inclining test, damage stability calculation, and ship operation.

Different from the document of capacity data mentioned above, the sounding table shall provide the location and size information of all tank

sounding pipes along with the liquid volume corresponding to each sounding in tanks with even, heel, and trim condition so as to provide the correct capacity information for the chief officer.

Visibility Plan

A drawing (shown in Fig. 5) checking if the blind sector forward of the bow, from the point of conning, satisfies or not the requirement of classification society. All the loading conditions from the preliminary or final stability calculation have to be considered.

Free Board Marks Plan

A drawing indicating the assigned freeboard mark and load lines for various drafts as well as the freeboard deck line (shown in Fig. 6).

The freeboard mark is composed of a ring and a horizontal line intersecting the ring. The letters on either side of the ring represent the classification society who assigned this mark on behalf of competent authority.

The load lines according to the ship's navigational area and season are represented by horizontal lines with a letter.

- Letter “S” stands for the summer load line.

Ship Overall Design,
Fig. 5 Visibility plan

Ship Overall Design, Fig. 6 Ship free board marks

- Letter “T” stands for the tropical load line.
- Letter “W” stands for the winter load line.
- Letter “F” stands for the summer freshwater load line.
- Letter “TF” stands for the tropical freshwater load line.
- Letter “WNA” stands for the North Atlantic winter load line.

Damage Control Plan

A drawing presenting all the information pertaining to ship’s damage controlling.

Such information include:

- Watertight boundaries of the ship.
- Locations and arrangements of all cross-flooding systems together with the locations of their valves and remote controls, if any.
- Locations of all internal watertight closing appliances.
- Locations of all the openings and their closure appliance whether on deck or on side shell.
- Location of all bilge and ballast pumps, their control positions, and associated valves.

Preliminary Trim and Stability Calculation

A calculation for all intended loading cases based on general arrangement, capacity plan, and data as well as preliminary lightweight result.

The trim and stability for each loading case with departure, midway, and arrival shall be checked to demonstrate the compliance with the criteria of applicable rules and regulations.

Preliminary Damage Stability Calculation

A calculation for all specified damage scenario based on general arrangement, capacity plan, and data as well as preliminary lightweight result.

The stability and final equilibrium waterline for each damage scenario for every loading case with departure, midway, and arrival shall be checked to demonstrate the compliance with the criteria of applicable rules and regulations.

Loading Manual

A document providing the similar contents as the preliminary trim and stability calculation, however, updated with approved lightweight data.

In addition, this manual should contain more information rather than preliminary trim and stability calculation such as:

- Instruction to Captain.
- Envelop of bending moment and sheer force.
- Draught limitations (in ballast, etc.)
- Load specifications for cargo decks.
- Cargo mass and cargo angle of repose restrictions.
- Cargo density and filling heights for cargo tanks.
- Restrictions to GM-value.

Definition

Ship propulsion system is the most vital component of marine power plant system, which

provides propulsion forces for ships to maneuver themselves. Most of ship propulsion systems may consist of main engine, shafting system, and propeller, which convert the energy of the fuel from main propulsion engine into useful thrust to propel the ship and match the ship resistance with the help of the shaft.

Types of Ship Propulsion System

Using the best type of propulsion system is vital to ensure a better safety standard for the marine ecosystem along with cost efficiency. Moreover, the type of propulsion system used in a ship depends on several factors such as speed, power, ship type, etc. According to power transmission mode, there are several forms of propulsion system enumerated as follows (Anthony et al. 2011).

Direct Drive Propulsion System

Direct propulsion system is the most commonly used on the ship, in which the power output from engine is translated to propeller directly through the shafting without decelerator or clutch. In this type of propulsion, the rotation speed of main engine and propeller are the same, thus operating of the ship can be done by altering the speed and direction of the main engine. Since the mechanical simplicity and easy maintenance, direct drive propulsion system is the most commonly used system on ships. Also, it has fewer energy losses. However, this type of system usually has big size and weight, and the speed is restricted by main engine when ship needs a very slow speed. Thus, direct drive propulsion system as shown in Fig. 1 is generally applied to large-scale merchant ship which usually incorporates large bore low-speed diesel engines.

Indirect Drive Propulsion System

Unlike direct propulsion system, the power transfer process of the indirect drive propulsion system from main engine to propeller shown in Fig. 2 contains some intermediate conversions, which results from the installation of intermediate devices such as clutch and decelerator. The installation of decelerator reduces the number of revolutions from the engine output in such a way that

Ship Propulsion System, Fig. 1 Direct drive propulsion system

Ship Propulsion System, Fig. 2 Indirect drive propulsion system

the system may derive maximum propeller efficiency.

The advantages of such system are the following: (1) the propeller can keep very low rotation rate without limitation from main engine, (2) because of the existence of clutch, changing over is not needed anymore, and (3) such a system is more convenient for reversing and setting shaft generator. However, with the additional procedures of energy conversion, the energy costs more, and the efficiency of the whole system decreases. Since the pros and cons, the indirect drive propulsion system is more common in small- and medium-sized ships, and it is also suitable for large-sized ships equipped with high-power medium speed diesel engines.

Electrical Propulsion System

In addition to two types of propulsion system mentioned above, another widely used propulsion system is electrical propulsion system. This relative new propulsion mode produces less pollution compared with conventional propulsion system. In this way, the propeller relates to the propulsion motor, which is driven by generator engine through main switch board as shown in Fig. 3. Some redundant shaft and bearing are omitted in electrical propulsion system. Thus, the space is saved. Also, the direction of the rotation of propeller is governed by altering the direction of current of electrical motor, which guarantees the ship maneuverability, and rotation can vary with more extensive range. However, the electrical

Ship Propulsion System, Fig. 3 Electrical propulsion system

propulsion system may cost extremely more than direct and indirect types in the initial cost and maintenance. Moreover, in the energy conversion process of the system, the mechanical energy is converted into electric energy and then into mechanical energy, which contributes to low efficiency of the whole system. Electrical propulsion system is commonly applied to icebreakers or engineering ships such as tug or dredger.

Shafting Transmission System

Shafting transmission system is an essential unit on a power-driven ship, which functions as the transmission converting the power from main engine to the propeller (Lee 2018). The useful thrust from the propeller is also converted to the ship through the transmission system. The shaft is manufactured from forged steel, completed with coupling flanges. Generally, the transmission system consists of various shafts (thrust shaft, intermediate shaft, tailshaft), bearings (thrust shaft bearing, intermediate shaft bearing, tailshaft bearing), and ultimately the propeller itself.

The propeller shaft usually connects the transmission inside the vessel directly to the propeller, passing through a sealing arrangement at the end of the tailshaft which connects directly to the propeller to complete system's arrangement.

Around the shafts are bearings, spacingly fitted along the length of the shaft, to bear the weight of the shaft to prevent shaft bending and constrain its radial motion. The bearings can also raise the shaft's axial bearing capacity while it holds the tensional forces from water repulsive. It is noteworthy that there is a thrust block, a specialized form of thrust bearing installed just aft the main engine, to support thrust shaft, resist the thrust of

the shaft, and transfer it to the hull of the ship. The thrust block itself is carried by bearing pads with the helical oil grooves cut into them. The pads faced with white metal are mounted in holders around a steel support, holding them against a machined collar on the drive shaft. The intermediate shaft bearing only has bottom bearing, but the aftermost tunnel bearing is the only one equipped with both top and bottom bearing shells since it has to offset the propeller mass and bear a vertical upward thrust of the tailshaft. The installation for carrying the tailshaft is called stern tube which is supported by stern tube bearing. The tube consists of a cast iron tube welded into the stern frame. And it is responsible for lubrication and sealing tasks arrangements of tailshaft.

During the time when the ship is moving, the imbalance rotatory motion of the main engine creates excessive excitation forces on the shaft which leads to undesirable axial vibration in the ship body. Meanwhile, shaft suffers from the inconstant cyclic torsional-bending vibrations which attributes to considerable hydrodynamic pressure in the longitudinal direction, so-called longitudinal vibrations. The longitudinal vibrations also cause the wear damage of thrust bearings. Moreover, the increasing torsional vibrations may generate large torsional stress on the shafting, which would be imposed the existing stress from torque transmission, axial stress, and longitudinal stress. The torsional vibrations mainly result from imbalance thrust of propeller. Besides, excessive vibrations in torsional, longitudinal, and axial modes and their coupled vibration forms are hostile and may lead to massive failures when operating shafting (Anthony et al. 2011). Thus, the reliability of the shaft is crucial to the ship navigation safety. The proper estimation of the dynamic performance of shaft is significant to guarantee the optional power delivery to the propeller and to minimize vibrations.

The torque M on the shafting can be calculated as follows:

$$M = 9.55 \frac{P}{n} \times 10^3 \quad (\text{N} \cdot \text{m}) \quad (1)$$

where n is the rpm with unit of r/min and P is the power translated by shafting. Meanwhile, the

thrust T delivered by shafting can be calculated as follows:

$$T = 1.94 \frac{P_p}{v} \eta_p \quad \text{kN} \quad (2)$$

where P_p represents propeller achieved by propeller, v is the ship speed, and η_p is the efficiency of propeller.

The shaft works under severe conditions, bearing force and torsion as shown in Fig. 4. In addition, the increase of load in the shaft system occurs owing to the influence of the propeller weight at the shaft end and effect of other attachments. Meanwhile, the journal rubs against the bearing when system is working. Also, journal and stern tube would be prone to corrosion if stern bearings are lubricated by seawater.

As mentioned above, owing to the rough condition, damage, moreover fatigue, would be frequent (Lee 2018). To reduce damage, the following conditions should be fulfilled: (1) the shaft must have enough strength and rigidity; (2) the conversion of power needs to be efficient; (3) the shaft should have good adaptability to hull deformation; and (4) torsional resonance is forbidden. Within the prescribed range of operation, (5) the shaft system should have good sealing, lubrication, and cooling performance; (6) the shaft system needs to be conveniently maintained and managed.

Propeller

Propeller Geometry

A marine propeller is the most common propulsor on ships, imparting momentum to a fluid which

generates the desired thrust to act on the ship (MAN 2018). Based on the torque or power generated, rotational motion will push the water backward and the ship forward.

A generic propeller has two to seven numbers of blades, depending on hull and shafting vibration frequencies, space-equally attached to the boss which is fitted at the end of the propeller shaft. The boss of the propeller is fitted with tapered propeller shaft for tight connection and then jointed with the propulsion mechanical system (Yeo and Ong 2014).

Blades are typically defined by a series of sections stacked at several radial locations. And these sections lie on cylindrical surfaces coaxial with the propeller shaft which also represents the rotation axis. View from aft, the outline of a blade is not symmetric about the generator line. The geometry of the propeller is for one skew angle for various requirements.

When propeller is rotating ahead, the front edge of a blade that enters water initially is leading edge, and the other is trailing edge. These two edges meet at the blade tip which is in the outermost position of the blade. The propeller radius refers to the distance between the tip and the centerline of shaft, while diameter is twice this distance. The size of the propeller is crucial for operator to access the require torque and thrust of the propulsion system. The longitudinal distance in a complete revolution of the propeller is particularly called pitch. Moreover, the governing point to form the pitch over the surface of the rotating cylinder volume as it rotates will form a helix line. The pitch angle is formed by pitch and base of cylinder surface which may have significant influence on the displacement of each rotation; see Fig. 5.

Ship Propulsion System,
Fig. 4 Shaft force transmission system

The face pitch ration which is one of main structural parameters of propeller as in Fig. 6 can be calculated as follows:

$$P/D = \text{pitch of generator surface/ diameter} \quad (3)$$

The pitch can be fixed or varied across the blade radius. For the latter, the propeller is called controllable-pitch propeller (CPP). A mean pitch may be quoted which is an average value over the blade. It is noteworthy that even for constant radial pitch, the pitch angle γ will change radially, from a large angle at the blade root to a small angle at the tip. Let r represent the local radius. The local pitch angle can be calculated as follows:

Ship Propulsion System, Fig. 5 Propeller geometry (Yeo and Ong 2014)

Ship Propulsion System, Fig. 6 Pitch and pitch angle

$$\tan \gamma = \frac{P}{2 \pi r} \quad (4)$$

Because water is pushed backward a distance by propeller, the actual advance distance of the ship h_a is less than pitch. The slip is $P-h_a$ and slip ratio S can be calculated as follows:

$$S = \frac{P - h_a}{P} \quad (5)$$

Moreover, propeller advance ratio of prop J is determined as:

$$J = \frac{h_a}{D}. \quad (6)$$

Types of Propeller

(1) Controllable-Pitch Propeller

As the name implies, in the controlled-pitch propeller, the pitch can be altered for different encountering conditions which is generally achieved with hydraulic mechanical and hydraulic arrangement or pistons. The changeable pitch to match the required condition is useful in changing the speed of the ship without rising or lowering the speed or rpm of the main engine and drive ship reversely without the necessity to alter the direction of rotation of the engine. Therefore, the maneuverability improves (faster response of speed change), and the loss in efficiency is smaller compared with fixed pitch propeller in astern condition. However, because of mechanical complexity, the cost of installation and maintenance will be higher, and it should be noted that the hydraulic

oil in the boss which is used for controlling the pitch may leak out resulting in pollution. Controlled-pitch propeller is extensively equipped in tugs, ferries, and icebreakers which need variable speed changing during the operation.

(2) Fixed-Pitch Propeller

The fixed-pitch propeller is designed by the way that the blades are permanently attached to the boss with fixed blade angles. The pitch of this type of propeller is unchangeable since the propeller is casted. The fixed-pitch propeller is generally designed for achieving maximum efficiency at only one speed of rotation with one horsepower input amount and one load condition. Meanwhile, the fixed-pitch propeller is robust and reliable since it does not consist of any mechanical and hydraulic arrangement as in controlled-pitch propeller which also tends to decrease costs of maintenance, installation, and operation. However, the maneuverability of fixed-pitch propeller cannot be as higher as controlled-pitch propeller. Thus, the fixed-pitch propeller is usually used to meet requirements of simplicity and lower weight and cost, such as usage in cargo and submarine.

(3) Contrarotating Propellers

These propellers rotate coaxial in opposite directions, as implied in Fig. 7. The upstream propellers are often slightly larger than aft one to take account of the slipstream contraction of the propeller wake and to avoid the aft propeller to

contact with the tip vortex of the upstream one. These propellers can recover rotational losses, more specific, by aft propeller which is often directly coupled with the main engine. Thus, they produce a higher efficiency compared with conventional propellers. But the mechanical installation is more complicated and expensive than conventional propellers as extra weight and complicated gearing and sealing arrangement, as well as more requirements of maintenance. Thus, the contrarotating propellers are hardly used in normal ships but torpedoes, submarines, and some motorboats.

(4) Ducted Propeller

The ducted propeller is the type of propeller fitted with a fixed nozzle. The nozzle is a hydrodynamic designed shroud shaped like a foil encircling the blade tips of a propeller, and it can help in improving the efficiency of propeller.

There are two types of ducts, the accelerating and the decelerating duct. With the former, the duct accelerates the flow inside the duct and hence augments thrust of the propeller. This type usually finds applications in highly loaded propellers and propellers with restricted diameters such as in tugs and trawlers.

With the decelerating duct propeller, the duct circulation reduces the inflow velocity, whereby loss of efficiency and thrust happen, while pressure in the propeller plane increases, resulting in reducing the cavitation risk and noise radiation. Thus, it is used in fast ships or military ships for

Ship Propulsion System,
Fig. 7 Contrarotating
propeller

perspective of cavitation risk and noise minimization.

Propeller Cavitation

Cavitation is the formation of vapor bubbles, which is the consequence of low local pressure level whenever local flow velocities become extreme due to Bernoulli's principle. This phenomenon can be explained as the process of nucleation in a liquid when the pressure drops below the vapor pressure (Pérez-Arribas and Pérez-Fernández 2018). After the pressure again increases to above the critical value, the vapor bubbles that formed around the nuclei begin to implode.

These vapor bubbles collapse within an extremely short time and can cause shock waves against the blades. It is the collapse of the bubbles that can physically damage the propeller blade surface due to very high energy influence and excite vibrations and noise due to pressure variations.

To control cavitation and improve the performance of ships, there are material and industrial ways. Using proper alloys which has great cavitation resistance (high flexibility and strength) can sufficiently reduce risk of cavitation. For industrial process, introducing the air-filled rubber membrane can prevent from cavitation to some extent as in Fig. 8. As it is called, this membrane placed directly after the propeller in the hull uses a pocket of air to prevent cavitation. The large substantial of air bubbles sprayed out over the propeller can be approximated as a single macro

bubble. Since the different stiffness characteristics of air and the small mass of seawater adjacent to the bubble, an isolate zone develops that has the ability to reduce the resonance frequency, which can raise the point at which cavitation is encountered. Thus, the probability of cavitation can be reduced during operation of a marine propeller.

Propeller Characteristics

The thrust, T , and torque, Q , depend on the propeller's diameter, D , revolutions, n , and speed of advance, V , together with the character of the fluid in which the propeller is operating and gravity. Nondimensional relationships between those factors can be expressed as:

$$T = f(D, V, n, \rho) \text{ and } Q = f(D, V, n, \rho) \quad (7)$$

Moreover, according to ship principle, if the engine power and ship velocity are known when the propeller is operating in open water, the propeller thrust T and torque Q can be calculated utilizing the nondimensional coefficients:

$$\begin{aligned} T &= K_T \rho n^2 D^4 \text{ (N)} \text{ and } Q \\ &= K_Q \rho n^2 D^5 \text{ (N} \cdot \text{m)} \end{aligned} \quad (8)$$

where K_T and K_Q represent propeller thrust coefficient and torque coefficient, respectively, which can be found in propeller data; see Fig. 9. ρ is the density of seawater; n is the propeller rotation

Ship Propulsion System,

Fig. 8 An example of propeller cavitation (Pérez-Arribas and Pérez-Fernández 2018)

Ship Propulsion System,
Fig. 9 An example of the
 K_T - K_Q - J chart

speed; and D is the diameter of the propeller. Propeller efficiency is defined as follows:

$$\eta_0 = \text{power output/power input}$$

$$= \frac{K_T}{K_Q} \cdot \frac{J}{2\pi} \quad (9)$$

For a propeller with definite geometry, thrust coefficient K_T and torque coefficient K_Q depend on advance ratio J . The varied relationship between these three parameters can be measured in experiment, as shown in Fig. 9.

Thrust and torque coefficients are typically nearly linear over a range of J . When propeller is working in a stable condition, $J(=h_p/D=V/nD)$ is constant and so are K_T and K_Q . The diameter of propeller D and density of water ρ remain unchangeable. Thus, as shown in Fig. 10, the thrust force $T \propto n^2$ and the torque $Q \propto n^2$. The power of propeller can be computed by $P_p = 2\pi nQ$. Hence, it is concluded that $P_p \propto n^3$.

The optimal matching of propeller rate, torque, and power to the main engine is very critical, which may limit the engine working under safe condition preventing it from overload. Diverse propellers with different diameter D and pitch P have different characteristic, which can determine how propeller and main engine work. In Fig. 11, it is hypothesized that the main engine runs at rated power P_b and rated engine speed n_b . The curve of selected propeller characteristic

Ship Propulsion System, Fig. 10 An example of the
propeller characteristics curves

Ship Propulsion System, Fig. 11 Matching of propeller
to main engine

following $P_p \propto n^3$ rule intersects rated power curve at point A. The engine operates stably at condition of point A; meanwhile the propeller achieves complete power output from main engine, represented by the curve I. If the ship encounters severe weather, hull roughness, or propeller roughness which augment the resistance, the propeller characteristic will shift to the left of the curve, such as the line on the curve II. Thus, the operating point moves from A to B which consequently harms the engine since the torque exceeds the limit. It should be noted that, in this situation, the consequences to the engine will result in power loss. The measures such as slowing down the engine need to be taken to prevent damage caused by overloading. Conversely, when assumed that encounters calm water, namely, light load such as in ballast, it is general that the propeller characteristic will move to right, represented by the curve III, and in this condition, the power and speed of engine both exceed rated values P_b and n_b , in which the engine also overload. The same measurement needs to be taken to ensure the engine functions properly.

Ship Recycling

Zunfeng Du

Department of Naval Architecture and Ocean Engineering, School of Civil Engineering, Tianjin University, Tianjin, China

Definition

“Ship recycling” means the activity of complete or partial dismantling of a ship at a ship recycling facility in order to recover components and materials for reprocessing and reuse, while taking care of hazardous and other materials, and includes associated operations such as storage and treatment of components and materials on site, but not their further processing or disposal in separate facilities (International Maritime Organization 2009).

The ship recycling industry is vital for both the shipping industry and the waste recycling industry. On one hand, it helps renew the global fleet of ships and balance the demand and supply of ships in the freight market; on the other hand, it recycles millions of tons of scrap material and contributes to the sustainability. Ship recycling is a complex industrial activity which is required to get rid of end-of-life ships that cannot be used for maritime transportation for various reasons (Jain and Pruyu 2017).

Scientific Fundamentals

Ship recycling is a highly polluting industry. Hazardous chemicals such as asbestos, PCBs, and heavy metals are released during the ship's dismantling and endanger both the environment and the personnel. Moreover, since companies rarely clean end-of-life ships prior to ship recycling, the ships often also exude toxic oils directly into the ocean. And, accidents are very prone to occur in the process of ship dismantling. It needs laws to ensure the implementation of HSE management system.

Contemporary International Law

An integral component of the shipping business, ship recycling is also a global industry. Several international hazardous waste management instruments do great impact on the ship recycling industry. The Basel Convention on the Control of Transboundary Movements of Hazardous Wastes and Their Disposal (1989), the primary international legal hazardous waste management law, as well as the Basel Ban and the Technical Guidelines for the Environmentally Sound Management of the Full and Partial Dismantling of Ships govern the transboundary movement of ships for recycling (Puthucherril 2010).

Elements of the 1982 United Nations Convention on the Law of the Sea (LOS Convention) are also relevant to shipbreaking. The International Labour Organization (ILO) has established standards to protect workers for occupational safety and health. Several IMO conventions on shipping and maritime safety are also apposite to ship recycling. These include the Convention on the Prevention of Marine Pollution by Dumping of Wastes and Other Matter (1972) (London Convention) and its 1996 Protocol, the Nairobi International Convention on the Removal of Wrecks (2007), the International Convention on the Control of Harmful Anti-fouling Systems on Ships (2001), the International Convention for the Control and Management of Ships' Ballast Water and Sediments (2004), and the International Convention for the Prevention of Pollution from Ships (1973) and its Protocol of 1978.

The most important among the IMO instruments having a direct bearing on ship recycling prior is the Hong Kong International Convention for the Safe and Environmentally Sound Recycling of Ships, 2009. The Convention embraces the "cradle to grave" concept for the purpose of addressing all environmental and safety aspects relating to ship recycling. It takes into account all aspects, from the ship's design stage onward to the end of the ship's life. It also includes the responsible management and disposal of associated waste streams in a safe and environmentally sound manner.

In December 30, 2013, the new EU new shipbreaking act came into effect. The bill applies to all existing ships, new ships, supporting products,

non-EU flag vessels moored at EU ports, and the dismantling of EU vessels. Many of its provisions are higher than the Hong Kong Convention. As per this regulation, all ships entering European Union (EU) ports as well as EU-flagged ships should have an inventory of hazardous materials (IHM). The requirements for an IHM are detailed than for the Hong Kong Convention's IHM, specifically concerning accuracy and comprehensiveness (The European Parliament and Council of the European Union 2013).

Ship Recycling Process

The entire process of ship recycling can be divided into three main phases or sub-processes, i.e., pre-cutting phase involving various surveys and other preparations for gas cutting, cutting phase where actual cutting of steel hull and machinery takes place, and finally the post-cutting phase involving sorting and segregation of materials (Du et al. 2018).

The pre-cutting sub-process comprises all the activities of the ship recycling process that take place before the actual cutting of an end-of-life ship starts. The pre-cutting sub-process can be opened up into various sub-processes such as removal of loose items; removal of liquids; removal of hazardous materials; removal of insulation, tiling, and flooring; and removal of cables and electrical equipment. Though vessel survey is also a part of pre-cutting process, it is not shown in the process diagrams because they are focused at showing the material flow through the ship recycling process.

The cutting sub-process is divided into primary cutting and secondary cutting. The primary cutting is the process where ship's hull is cut into ferrous blocks and nonferrous items such as zinc anodes, copper pipes, valves, etc. are taken apart. During primary cutting, ship's machinery is cut from the base either to be sold in the secondhand market or to be fed as an input for secondary cutting, if it is of no value to the secondhand market. The process of primary cutting is executed using mainly gas cutting torches.

The post-cutting sub-process comprise "pick-up and storage," "separation," and "segregation and transport" sub-processes.

The specific steps can be divided into seven steps.

Step One: Vessel Survey

Diagrams of all compartments, tanks, and storage areas are used (or prepared, if not available) to identify areas that may contain hazardous materials such as fuels, oils, asbestos, PCBS, lead, and other hazardous wastes. Sampling is carried out to enable recycling facility to decide disposal options of certain items containing hazardous materials.

Step Two: Removal of Fuel, Oil, and Other Liquids and Loose Items

Next step is the removal of loose items and fuels, oils, and other liquids (e.g., bilge and ballast water) from the ship. During the vessel scrapping process, water may accumulate due to rain, firefighting activity, or use of hot work cooling water and will have to be properly removed. Loose items include furniture, lifesaving equipment, etc.

Step Three: Removal of Asbestos, PCBS, and Other Hazardous Materials

Both asbestos-containing materials (ACMS) and PCBS are usually removed in two stages. First prior to cutting away a section of the vessel, from areas that are to be cut as and when accessible and then after the vessel section has been moved to shore, remaining ACMS and PCBS can be removed.

Step Four: Removal of Insulation, Cables, and Equipment

Fixtures, anchors, chains, and small equipment are removed first. Large reusable components (e.g., engine parts and other machineries) are removed as they become accessible. Propellers also may have to be removed so that the hull can be pulled into shallow water insulation and cable is also removed before cutting commences.

Step Five: Surface Preparation for Cutting

Before cutting the metal, the surfaces require specific cutting preparation. The paint or preservative coatings are stripped from surfaces by grit blasting or flame removal, in order to prevent exposing

workers to toxic metals and volatile components of paint.

Step Six: Metal Cutting

During the cutting phase, the upper decks, superstructure, and systems are cut first, followed by the main deck and lower decks. Metal cutting is usually done manually using oxygen-fuel cutting torches but may be done with shears or saws for nonferrous metals. Typically, as large parts of the vessel are cut away, they are lifted by crane to the ground where they are then cut into specific shapes and sizes required by the foundry or smelter to which the scrap is shipped.

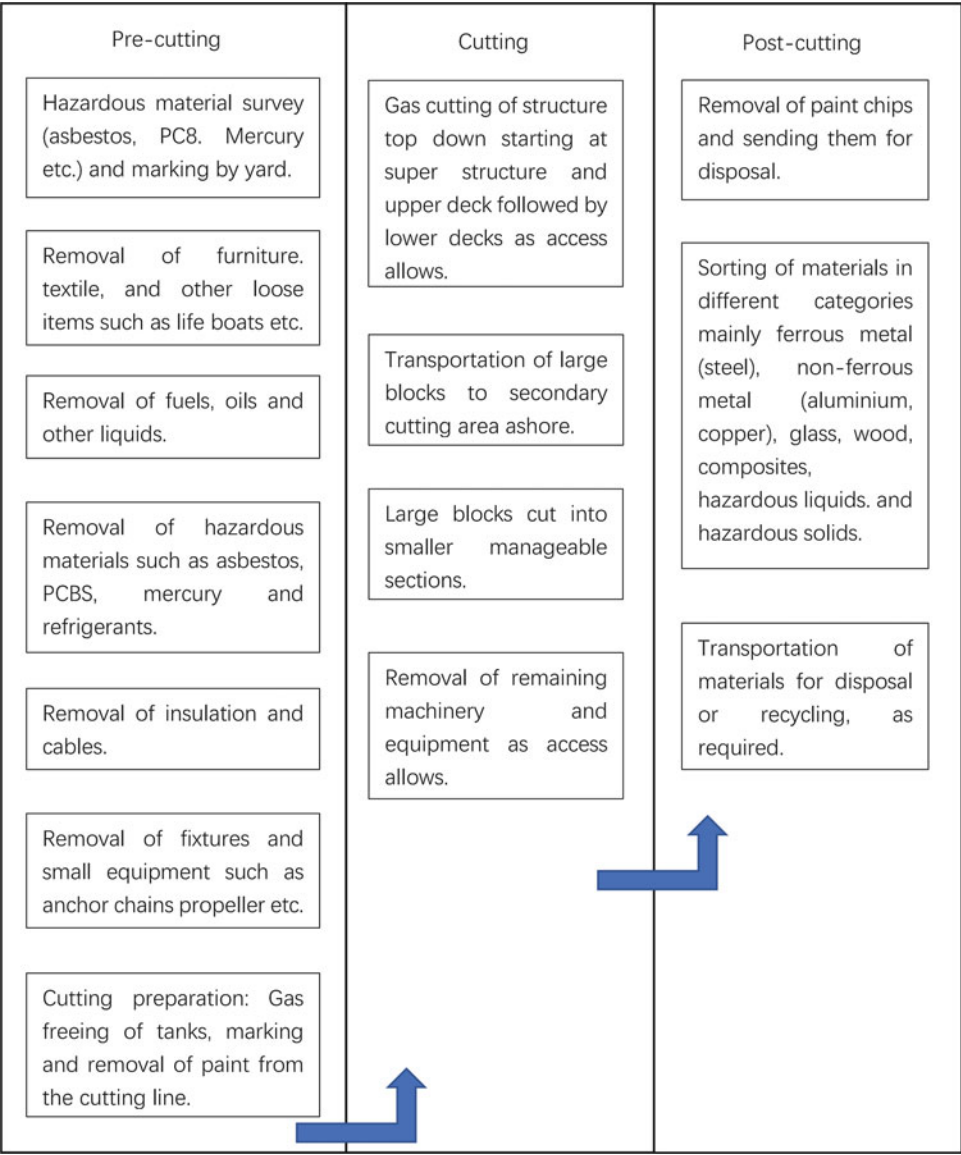

Step Seven: Resale, Recycle, or Disposal

During the post-cutting phase, various material streams from the ship are segregated for resale, recycle, or disposal.

In a word, the entire process of ship recycling can be represented by the following figure (Fig. 1).

Problems of Ship Recycling

The process of ship recycling is essentially the recycling of ship materials. The recycling process may lead to inevitable problems threatening the safety and health of the workers, as well as polluting the ambient environment. Especially in some developing countries, the working conditions on many beaching yards are very poor. Workers hardly wear shoes or safety clothes; they are unskilled and untrained and have to face dangerous situations like fire, explosions, exposure to toxic materials, heights, and falling debris. Accidents causing injuries, permanent disabilities, and even fatalities are a common phenomenon. In short, these workers risk their lives for a low salary. The environment is also affected due to the way these ships are dismantled. Because the ships are scrapped on the beach, all sorts of harmful liquids and heavy metals enter the soil and the sea. The effect on the environment is huge on some of the recycling yards. These issues are collectively called as health, safety, and environmental (HSE) problems.

Ship Recycling, Fig. 1 The entire process of ship recycling

Improvement of Ship Recycling

In order to deal with these problems of ship recycling, design for recycling can be a great way. Instead of only looking at altering the process of recycling a ship, design for recycling addresses the ship’s entire lifetime. The idea is to implement changes to the design of a ship, which make recycling easier and safer.

The three most promising ideas are “reverse production”, “accommodation modularization”, and “resigning the fuel tanks”.

The first concept is “reverse production.” The idea of this concept is to reverse the section building process in ship recycling. The ship must be divided and dismantled in blocks. In the design and engineering phase, the dismantling blocks in

which the ship must be divided during the recycling phase must be selected. The concept also introduces lifting supports which must be fixed to each dismantling block during the building phase itself. The dismantling blocks must be divided in such a way that they do not exceed a weight of more than 500 tons. This is the minimum crane capacity assumed to be available at the shipbreaking yards.

Recycling of the accommodation has always been problematic. In the past, asbestos was commonly used; this is prohibited nowadays. Though, toxic heavy metals are still used which endangers the health of workers. Another problem is that only few materials from the accommodation are recycled, affecting the environment. The concept of modular accommodation builds upon the existing research done by Fikkert, Otheguy, and Durmisevic on modular accommodation on off-shore platforms. In this case, the accommodation is designed to be recycled and takes the recyclability of the materials into account.

Redesigning the fuel tanks is the third and last concept. One of the most dangerous jobs during ship recycling is cleaning and scrapping the tanks. The heavy fuel sludge has to be manually removed by the yard workers. Because the fuel tanks are confined spaces, with a lot of small and sharp corners, this is a difficult process. This concept focuses on creating an easier and safer cleaning process. A fuel tank is redesigned with corrugated bulkheads and trapezoid stiffeners to reduce the amount of difficult-to-clean places and to improve the ease of cleaning. An addition to the physical redesign of the fuel tank is an automatic cleaning system. The tank is designed with appropriate manholes, to enable the use of such a system. This machine works best in wide spaces, which are created in the new tank design. Because of this automatic cleaning system, no workers have to clean the tank manually, which reduces some health and safety issues significantly.

Key Applications

An activity as old as shipbuilding, ship recycling is an essential and integral component of the

shipping business. Once they have outlived their use, ships have been subjected to the axe to recover useable materials. However, with the advent of large modern ships with diverse structural complexity, the ship recycling industry became complicated and dangerous. Till the 1970s, large shipyards in the USA and in Europe performed ship recycling. With mounting economic costs for safe demolition of ships, industrialized countries found a convenient way to dispose of obsolete ships – pack them off to the developing world where there is a great hunger for steel for development activities.

Initially, the industry relocated to Korea and Taiwan Province of China. By the early 1990s, realizing the dangers which the activity entailed, they followed the West in discouraging ship recycling. Thereafter, business gravitated primarily to the beachheads of Third World countries, namely, India, Bangladesh, and Pakistan.

A ship can be recycled by employing different types of ship recycling methods in different parts of world. The methods are similar in most aspects wherein ships are cut apart to retrieve materials and components. The major difference between various methods is firstly by the way ships are docked and secondly by the level of mechanization employed. There are four general methods to dock ships for recycling, i.e., beaching, slipway, alongside, and dry dock. The level of mechanization can be characterized as the non-mechanized process, the highly mechanized process, and the intermediate process. The non-mechanized process is a labor-intensive process which uses a strong labor force and is generally found in the Indian subcontinent recycling yards. The highly mechanized process uses a small amount of labor force and is found solely in Western countries. The intermediate process uses some equipment but still maintains a significant amount of labor force and is generally found in Turkey, China, or even at some dismantling facilities in the USA.

General Methods to Dock Ships for Recycling

Beaching

Beaching is the term generally used for dismantling ships at grounded conditions on the intertidal

zone. Ships are run ashore, as far up the beach as possible, at high tide to leave them grounded at low tide. Ships often don't make it to the beach and are stranded on the mudflats. They are then pulled higher onto the beach using chains or heavy steel wires attached to large winches on the beach. As steel blocks and other equipment of a ship are progressively cut in the intertidal zone using cutting torches, ships become lighter which are then pulled up the beach by winches. Large blocks may also be cut from the ship, released onto the mudflats, and dragged individually by the winches on to the shore. Once on shore, everything is cut into smaller pieces as required by end buyers.

The beaching method is used to dismantle about two-thirds of the world's end-of-life ship capacity, i.e., 66% in terms of gross tonnage. The main locations include Chittagong in Bangladesh, Alang in India, and Gadani in Pakistan. These areas have a very large tidal difference and extensive mudflats which are utilized to drive ships up the beach. The beach is generally divided into plots of about 50 m wide and up to 100 or 150 m deep. A major issue with dismantling ships on tidal mudflats is that any spills of oil or cargo remaining on board are likely to be swept out to sea by the next tide.

Slipway

This method is a modification to the beaching method and is also called as nontidal beaching. The major difference between beaching and the slipway method is that of tide. It is practiced in areas with a low tide difference, especially in Turkey. Other than Aliaga in Turkey, slipway recycling is practiced in many small-scale historical recycling locations such as Inverkeithing in the UK and other locations in Europe and USA today. In the USA slips are generally 400–700 ft long and 100–120 ft wide at the entrance.

The ship is still beached against the shore or, preferably, a concrete slipway extending to the sea. In either case, the lack of racing tides provides an element of control which means that any accidental spillages can reasonably be contained. It is generally acknowledged that the low tidal difference and improved access to the hull and the

working area offer advantages for safe and environmentally sound operations compared to the beaching method. About 4% of the world's recycling capacity uses nontidal beaching method for ship recycling at Turkey.

Normally pieces are removed from the ship by mobile crane working from the shore. In this method also, the ship is dragged up the shore as it is lightened but because the tide is constant and a permanent, predictable, and stable waterfront exists where the lifting and access operations take place.

Alongside

The alongside method, also referred to as quayside, pier side, or floating method, is a method to dismantle ships that are afloat and moored along wharfs, jetties, or quays and/or moored offshore. Cranes and either automated cutting gear such as mechanical shears or gas cutting torches are used to reduce the ship in a planned and structured manner. The process is top down: the superstructure and upper pieces are removed first, and then the work continues along the ship into the engine room until only the double bottom is left. This last part of the ship, an empty floating hull called the canoe, is reduced to the extent possible while afloat and then either taken out as a whole or further cut into pieces in a dry dock. This method is mainly practiced in China, the USA, and Belgium. China provides about 28% of the world's recycling capacity in terms of end-of-life ships' gross tonnage.

During alongside recycling, local impact of any pollution is likely to be increased since there is no tidal dispersal effect. However, this means that concentrations can be properly monitored, contained, and cleaned if necessary.

Dry Dock

In this method ships are dismantled at a dry dock, floating dock, or a slipway which has a lock gate and an impermeable floor structure. This method is the safest and cleanest way of recycling a ship because chances of polluting surrounding waters by accident are virtually nil as everything is contained within the dock. The dock is cleaned before it is flooded for dismantling the next ship in order to avoid accumulations of contaminants.

The only downside with this method is that it is the most costly method of recycling a ship which makes it most scarcely used method. One of the main dry-dock recycling locations is Leavesley International's facility in Liverpool in the UK.

Definition

The Ship Recycling Facility Plan (SRFP) is the main document relied upon by Competent Authorities (or an organization recognized by them) when authorizing a Ship Recycling Facility. The convention and subsequent regulations for the SRFP are in place to ensure that recycled ships pose no threat to either human life or the environment during or after they have been recycled.

Scientific Fundamentals

In accordance with the 2011 Guidelines for the Development of the Ship Recycling Plan under the Hong Kong Convention, and the EU Ship Recycling Regulations, ships that are to be recycled require a Ship Recycling Plan, provided by the Ship Recycling Facility, who must also evidence a plan for how they safely dispose of the ships under their Ship Recycling Facility Plan (SRFP).

The plan should fully describe the operations and procedures that are in place at the Ship Recycling Facility to ensure compliance with the Hong Kong Convention and the EU Ship Recycling Regulations.

The SRFP should also demonstrate knowledge and understanding of

- All applicable statutory and regulatory requirements.
- A strong commitment to worker health and safety and protection of the environment.
- The operational processes and procedures involved in ship recycling.
- How the requirements of the Convention will be met.

An SRFP should also provide information regarding the organizational structure and management policies of the Recycling Company, an overview of the Ship Recycling Facility and their methodologies relating to shipping recycling.

Requirements for Recycling Facilities

Recycling facilities authorized to recycle ships will be expected to produce a ship-specific Ship Recycling Plan on the basis of information provided by the shipowner (IHM, ship's plans and manuals), taking into account the guidelines of the HKC.

Recycling facilities will also be required to produce and operate in accordance to a Ship Recycling Facility Plan that is developed considering the relevant guidelines of the HKC.

To be authorized, recycling facilities will have to comply with the provisions of the HKC:

1. "Operate from build structures"
2. Demonstrate "the control of any leakage, in particular in intertidal zones".
3. Ensure "the handling of hazardous materials, and of waste generated during the ship recycling process, only on impermeable floors with effective drainage systems".

These three requirements are products of the negotiations between the European Council and the Parliament. A key policy of the Parliament was to achieve an outright ban to beaching. The second and third of the above three provisions prescribe requirements that will have to be met regardless of the recycling method used, while the first requirement for operating "from build structures" is imprecise and ambiguous and is a compromise devised to accommodate political sensitivities in the negotiations.

Since the conclusion of the negotiations, the Rapporteur of the Parliament has chosen to treat the outcome as confirmation of a ban to beaching. He issued in July 2013 a celebratory press release, stating: "These standards effectively mean the end of beaching where ships are simply taken apart on a beach, with scant regard for human health or the environment. . . . The new law will make it compulsory for ships to be recycled from built structures only and in such a way that all hazardous materials are fully contained. As this is impossible on a beach, the practice of beaching is de facto forbidden." More recently, on the occasion of the formal adoption of the ER by the Parliament on

22/10/2013, a further press release stressed that: "Plans agreed with EU ministers to end the scrapping of old EU-registered ships on third-country beaches . . .", and also: "During the negotiations, Parliament strengthened the proposed requirements, inter alia by obliging ship-recycling businesses to operate in built structures . . .".

Reportedly, the European Council seems to have understood that it would be an absolute blunder to exclude the South Asian ship recycling market from the ER and from the options available to European shipowners. Moreover, ship recycling experts are very clear that there is no contradiction between good quality beaching, safety, and protection of the environment. Apparently, it was for these reasons that the Council refused to agree to ban beaching. Such a ban would lead to a new massive evasion of the ER by owners and probably to a total disinterest by South Asian countries to consider acceding to the HKC, thus torpedoing its prospects of entry into force. Ironically, the ban for which the Greens are fighting, would only serve the commercial interests of substandard recyclers and of the Shipbreaking Platform, who, in this way, will continue to have something to do.

The European Commission will implement the ER and will be required to put to practice its requirements. The ER provides the option to the Commission to issue technical guidance notes so as to facilitate the certification of recycling facilities (Art. 15(4)). The Commission is expected to develop such guidance in 2014 and in so doing to interpret the meaning of "from build structures." The ER, like the HKC, requires the recycling facility to formally report its readiness for the commencement and also the completion of recycling of each ship under ER's scope. Interestingly, whereas the HKC requires the facility to report to its competent authority, ER requires the facility to report to the administration of the flag State, as Europe has no jurisdiction over competent authorities of recycling States outside the European Union.

There is one further important, but understandable, difference between ER and the HKC. Whereas according to the HKC, the authorization of recycling facilities is a matter for the competent

authorities of the recycling State, the ER could not expect the authorities in countries outside the European Union to enforce the ER, and for this reason it has developed the new mechanism of the “European List of ship recycling facilities”, Fig. 1 is example format of facility information in SRFP.

Facilities located in a European Member State will be authorized by the competent authorities of that Member State who will then notify the Commission of the facilities that it has authorized. The Commission will then include these facilities in the European List that will establish and publish in the Official Journal and on its website no later than 36 months after the ER’s entry into force. On the other hand, facilities located in third countries will have to apply individually to the Commission for their inclusion in the European List. Together with their application, they will provide evidence showing that they meet the requirements of the ER. The compliance of individual facilities “shall

be certified following a site inspection by an independent verifier with appropriate qualifications.” Furthermore, the facilities will have to “accept the possibility of being subject to a site inspection by the Commission or agents acting on its behalf.” The renewal of the certification and inclusion in the European List will take place every 5 years, subject to a mid-term review confirming compliance.

Definition

A Ship Recycling Plan is a living document detailing the specific recycling process information relating to a specific marine vessel.

In accordance with the 2011 Guidelines for the Development of the Ship Recycling Plan under the Hong Kong Convention, and the EU Ship Recycling Regulations, ships that are to be recycled require a Ship Recycling Plan. Additionally to the regulations, the benefits of ship recycling in reducing human and environmental impacts include:

- Recycling reduces the need for mining – an environmentally damaging practice.
- Some materials can be recycled infinitely.
- Contributes to the sustainable development of the shipping industry whilst minimizing and reducing the current environmental impact on oceans and seas.
- Deters the practice of “beaching” and protects workers from dismantling without using PPE.
- Control, monitor, and reduce the impact of IHMs on local environments that disrupt biodiversity and can affect the surrounding environments impacting on wildlife, farming, and communities.
- To support our clients in meeting the regulatory requirements our team produce internationally recognized Ship Recycling Plans and

support you through the process with expert advice and guidance.

Scientific Fundamentals

Ship recycling means the activity of complete or partial dismantling of a ship at a ship recycling facility in order to recover components and materials for reprocessing and re-use, while taking care of hazardous and other materials, and includes associated operations such as storage and treatment of components and materials on site, but not their further processing or disposal in separate facilities. A Ship Recycling Plan shall be developed by the Ship Recycling Facility(ies) prior to any recycling of a ship, considering the guidelines developed by the Organization. The Ship Recycling Plan shall:

1. Be developed considering information provided by the shipowner.
2. Be developed in the language accepted by the Party authorizing the Ship Recycling Facility.
3. Include information concerning inter alia, the establishment, maintenance, and monitoring of safe-for-entry and safe-for-hot work conditions and how the type and amount of materials including those identified in the Inventory of Hazardous Materials will be managed.
4. Should be either explicitly or tacitly approved by the Competent Authority authorizing the Ship Recycling Facility. The Competent Authority shall send written acknowledgment of receipt of the Ship Recycling Plan to the Ship Recycling Facility, Ship Owner, and Administration within 3 working days of its receipt.
5. Once approved in accordance with paragraph 4, be made available for inspection by the Administration, or any nominated surveyors or organization recognized by it.
6. Where more than one Ship Recycling Facility is used, identify the Ship Recycling Facilities to be used and specify the recycling activities and the order in which they occur at each authorized Ship Recycling Facility.

Framework of SRP

The responsibility for developing a comprehensive SRP rests with the Ship Recycling Facility,

although development of the SRP is a cooperative effort between the Ship Recycling Facility and the shipowner. The Ship Recycling Facility is best placed to understand and describes the methods and procedures that it uses in its recycling operations and it has knowledge of the available facilities and capabilities for the safe and environmentally sound management of all hazardous materials and wastes generated during recycling, of the skills and capabilities of its workforce and the availability of local support services, and of the relevant national laws and regulations that apply to the facility and its activities, including the activities which it is approved to perform under its DASR. A sample cover page for the SRP is included in the appendix. The body of the SRP should include a more detailed narrative of the ship-specific recycling elements.

The SRP should describe how the Ship Recycling Facility will recycle the specific ship in a safe and environmentally sound manner, covering the recycling process steps and their sequence over the entire process. Any processes or procedures that deviate from the SRFP and are specific to the ship should be described in detail in the SRP.

Where more than one Ship Recycling Facility is used, SRPs should be prepared separately, in principle, by each of the Facilities involved, according to their respective duties and indicate the order in which the activities will occur.

1. Prearrival Elements

The SRP should include a description of any specific preparatory work that should be carried out. The SRP should clarify whether and to what extent any preparatory work – such as pretreatment, identification of potential hazards, and removal of stores – will take place at allocation other than the Ship Recycling Facility identified in the SRP. The extent to which such preparatory work will be covered in the SRP will depend upon the capability of the authorized Ship Recycling Facility and the scope of the agreement with the shipowner. In the case of a tanker, the ship should arrive at the Ship Recycling Facility with cargo tank and pump room(s) in a condition that is ready for certification as Safe-for-entry, or Safe-for-hot work, or both.

The Ship Recycling Facility should plan appropriately for the ship's arrival. The SRP should include the location where the ship will be placed during recycling operations and a concise plan for the arrival and safe placement of the specific ship to be recycled.

2. Arrival of Ship

The SRP should describe the procedures that the Ship Recycling Facility will follow to conduct a walk-through (on-board check) of the vessel to identify any potential environmental or safety issues. The Ship Recycling Facility should verify whether safe access and egress have been provided for and that the SRP is in place throughout the ship recycling process. It is recommended that the Ship Recycling Facility should mark the location of the known hazardous materials. Any specific items or locations on board whose hazardous characteristics are uncertain should be marked for additional sampling as necessary.

3. Management of Hazardous Materials

The SRP should include information on how the type and amount of hazardous materials will be managed, as required by regulation 9.3 of the Convention and specify the facility's approach for managing each hazardous material. Special attention should be paid to the types and quantities of hazardous materials on the ship. If ship-specific conditions require deviation from normal practices for managing hazardous materials, the appropriate ship-specific measures should be described in detail in the SRP. In order to avoid confusion, it is recommended that the SRP should use the same nomenclature and identification scheme as those included in the IHM.

The SRP should also contain additional information on the management of hazardous materials as required in Appendix 5 of the Convention (also known as the DASR). Specifically, the SRP should describe where the hazardous materials are to be processed or disposed of if the operation is not being conducted at the Ship Recycling Facility. The SRP should state that the removal of hazardous materials will be undertaken by responsible personnel who are trained and authorized to do so.

4. Safe-for-Entry and Safe-for-Hot-Work Procedures

Regulation 9 of the Convention requires the SRP to include information concerning the establishment, maintenance, and monitoring of safe-for-entry and safe-for-hot-work procedures. The Ship Recycling Facility is encouraged to review the Facility Guidelines, as they contain specific technical recommendations to address these important safety issues.

While the SRFP will describe general procedures on how the Ship Recycling Facility will achieve safe atmospheric conditions during the ship recycling process, the SRP should describe in detail how safe-for-entry and safe-for-hot-work procedures will be implemented on the specific ship, taking account of such features as its structure, configuration, and previous cargo.

5. Dismantling Sequence

An important component of the dismantling sequence is the removal of hazardous materials to the maximum extent practicable prior to and during cutting activities. Depending on a number of factors, including the age of the ship and the quantity of hazardous materials present, it may be impossible to remove all hazardous materials prior to the start of cutting activities. The SRP should include a dismantling sequence that is ship-specific and takes into account the cutting operations and locations of hazardous materials.

6. Other Necessary Elements

In addition to the elements described above, the SRP should include any ship specific processes and/or procedures that will be necessary to recycle the ship and that are not fully covered in the SRFP. For example, a Ship Recycling Facility may need to use additional workers or subcontractors, or they may need additional equipment to deal with unique aspects of the ship. Such ship-specific processes/procedures may take into account the technical guidance manual to be developed by the Organization.

7. Attaching a Copy of DASR

The Ship Recycling Facility should attach a copy of the DASR (Document of Authorization to conduct Ship Recycling) to the SRP (See Fig. 1).

Ship Recycling Plan Summary of information on ship and Ship Recycling Facility

This Ship Recycling Plan was developed in accordance with the Hong Kong International Convention for the Safe and Environmentally Sound Recycling of Ships, 2009 (the Convention).

Ship information

Name of ship	
Distinctive number or letters	
Port of registry	
Gross tonnage	
IMO number	
Name and address of shipowner	
IMO-registered owner identification number	
IMO company identification number	
Telephone number

Ship Structural Design

Xian-Zhong Wang and En-Hui Xu

Departments of Naval Architecture, Ocean and Structural Engineering, School of Transportation, Wuhan University of Technology, Wuhan, People's Republic of China

Synonyms

Hull structure design

Definition

Ship structure design is to select the appropriate structural materials and structural forms and determine the size and connection of all components after the overall design (determining the main dimensions of the ship, the hull profile, and the overall layout of the ship) is completed. Ship structure design is to ensure that the ship has

enough strength, stiffness, stability safety, and other requirements, so that the structure has the best technical and economic performance.

Scientific Fundamentals

Ship Structural Design System

Ship structural design is generally carried out in three stages with the design process of the whole ship: preliminary design, detail design, and production design. Complete different tasks at different stages:

- Preliminary design: According to the approved technical specifications, the overall structural design principles (structural arrangements, structural forms, etc.) are analyzed and compared. Theoretical estimation of the arrangement and size of major components, the typical midship section drawings, and hull steel weight estimates are given.

- Detail design: The design is based on the decisions made during the preliminary design. At this stage, the technical problems in the structural design are fully solved, including determining the arrangement, size, and connection of the components. Design drawings and documents to be reviewed are submitted to the classification society. These designs take into account the fitting arrangement and hull block assembly process.
- Production design: According to the detailed design drawings approved by the classification society, all technical preparations for the construction of the hull structure, such as construction details, process measures, and assembly sequence of each component and component connection, are determined.

Design Procedure of Structures

Not only the ship structural design but also general structural design is carried out in accordance with the procedure shown in Fig. 1 (Yasuhisa Okumoto et al. 2009).

Ship Structural Design,

Fig. 1 Sequence of structure design (Yasuhisa Okumoto et al. 2009)

The design of the ship needs to meet the requirements for the type and quantity of cargo loaded, navigation area, sailing speed, endurance, or new type of ship. Then a preliminary general arrangement is to be prepared based on these requirements.

The estimation of the forces applied to the structures shown in Fig. 1 means that the ship is placed on a wave and the establishment of static loads including buoyancy, weight of ship, cargo weight, and the estimation of dynamic loads such as wave load and exciting force. The wave load is a related to ship type, wave elements, and calculation status (relative position of ship and wave).

In Fig. 1 the design flow, shown in vertical arrows, is based on standards and research results that are supplied to the designers by outsiders. Since the setting of the forces acting on the ship structure affects the design very much, the ship structural designer should always pay attention to the research of these contents.

In the step of modelization of strength response calculation, the correct structural failure mode should be applied. Not only theoretical knowledge but also observations experienced on actual failures are necessary in estimating the failure modes correctly.

The next step is to calculate response calculation for the forces applied. The traditional calculation assumes that each structural member is a simple beam fixed at both ends. In recent decades, computers can be used to model the entire structure and analyze the estimated forces.

For the allowable limit, there are allowable stress, allowable deformation, allowable amplitudes of vibration, and allowable reliability (Yasuhisa Okumoto et al. 2009). In practical applications, these allowable limits are based on ship design, construction, and operational experience, as well as accumulated static load measurements and voyage test results of actual ships, determined on the base of safety and economy. These limits are usually stipulated by specialized agencies such as the classification society's rules. The ship structural designer should pay special attention to them. Any changes in the method of load estimation must be followed by modifying the allowable limit.

Due to the different effects of structural damage on the hull, different structures have different importance. Therefore, there are different safety factors for different structures.

If the calculated response according to the above steps is within the allowable limit and satisfies reality, the shape and scantling of the structure should be accepted and decided. If these values are not moderate, further factors must be considered and verified repeatedly to make it meet the requirements.

In addition, material that is not depicted in Fig. 1 plays an important role in the design of ship structures. Mild steel for ships that is mainly used in the construction of ships has its excellent properties, toughness, robustness, weldability, and low price. The ship structural designer can use it without any special attention. However, nowadays high tensile steel is becoming more common as a shipbuilding material. When the high tensile steel and other special materials are used as shipbuilding material, the hull structure designer must pay careful attention to these materials.

Structural Design Quality Indicators

At present, the production technology of the shipbuilding industry in the world is developing in the direction of mechanization, automation, and integration. Improving the structural design requirements of ships has become a very important issue in the shipbuilding industry. Ship structure design shall ensure that the ship meets the following requirements when applied:

- Safety: The structure should be able to withstand the various possible loads during normal use and still maintain the necessary overall stability when accidental events occur.
- Operational suitability.
- Overall compatibility: In the design of the ship, the structural design must be coordinated with the design of the general, turbine, electrical, and other aspects to ensure that the ship has good performance in all aspects.
- Durability: Durability is the ability of a structure to maintain its original structural efficiency level. In other words, the structure can

be used for a predetermined number of years under normal maintenance conditions.

- **Manufacturability:** The designed structure must be easy to construct and ensure construction quality while minimizing the amount of construction work to reduce manufacturing costs.
- **Economy:** For civil ships, the general goal of the design is to make the ship the most economical benefit throughout the life of the ship.

Key Technology

Ships are often operated under high environmental conditions such as high speed, strong water flow, and strong air flow. The ship structure design must consider not only the longitudinal strength, local strength, and structural stability of the ship but also vibration, shock, and noise. It can be seen that the ship structure design is a subject area with high technical content and difficult design. In order to properly design the ship structure, it is necessary to understand the characteristics of the hull structure and the loads acting on it. Therefore, determining the ship's load, strength calculation, selection of suitable materials, and connection methods is the key to the ship structure design.

Structural Design Load

When considering the load features where the load is transmitted gradually and continuously from a local structural member to an adjacent bigger supporting member, the best way to categorize loads on the hull structure is as follows (Yasuhisa Okumoto et al. 2009).

- **Longitudinal strength loads:** Longitudinal strength load means the load concerning the overall strength of the ship's hull, such as the bending moment, shear force, and torsional moment acting on a hull girder. If the longitudinal strength loads exceed the upper limit of longitudinal strength for the hull, the hull will be bent or twisted. Therefore, the longitudinal strength load is one of the most important loads when calculating the overall strength of a hull structure.

Longitudinal strength loads may be divided into two categories: static longitudinal loads and dynamic longitudinal loads. Static longitudinal loads are induced by the local inequalities of weight and buoyancy in the still water condition. For instance, differences between weight and buoyancy in longitudinal direction cause a static bending moment and a static shear force, and asymmetrical cargo loading causes a static torsional moment. Dynamic longitudinal loads are induced varying loads and impact loads by waves. When the ship is on top of a wave crest in head sea condition, it causes a "hogging" bending moment and a shear force. When in a wave trough, a "sagging" bending moment and shear force are experienced, as indicated in Fig. 2.

Usually the "slicing method" which is a linear method for slender hulls is used to calculate the wave-induced shear and bending moments. In the slicing method, the hull is divided into "sheets", and the loads of each of the sheets are calculated, such as additional

Ship Structural Design,

Fig. 2 Vertical bending due to waves (Yasuhisa Okumoto et al. 2009)

inertial forces, wave forces, and Froude forces. The comparison between the result of slice method calculation and the test result shows that the accuracy of the wave load acting on the hull girder can meet the engineering requirements. So far, many scholars have done a lot of research and improvement work on the sectioning method, including nonlinear effects (Jensen and Pedersen 1978), three-dimensional effects of the ship's mast, and so on. Due to the action of waves, structures near the static side of the ship should be submerged or exposed to water, and necessary corrections must be made. Recently, the three-dimensional Green function method and the Rankine source method have been widely used to calculate wave loads in hulls. Newman (1990), Noblesse (1982), and Chen et al. (1995) have done a lot of work in this area and proposed an efficient numerical solution of the Green function. The Rankine source, which is the surface element method that began in aviation (Hess and Smith et al. 1962), is used as the Green function to solve the numerical calculations around the three-dimensional object potential flow.

The above methods are to calculate the actual load acting on the hull structure. However, in the normal hull design, the hull structural strength calculation and analysis are carried out according to the loading method specified by the classification society and in

accordance with the loading method prescribed by the classification society.

Wave impact loads can be divided into two loads: (a) impact force induced by slamming and (b) impact force of green seas on the deck. With rough sea conditions, linear theory cannot be applied, since the calculated results of ship motion and dynamic loads are influenced by the wave impact force and/or by the nonlinear effect of the vertical change of ship breadth at each cross section. These impact loads can contribute to the increase of longitudinal loads, for they may generate both an additional bending moment and shear force in the hull girder. Recently, many scholars have published articles using finite element, boundary element method, and finite difference method to calculate impact load, but the actual application is far from enough.

- Transverse strength loads: The transverse strength loads represent the loads which act on transverse members and cause structural distortion of a cross section. Transverse strength loads include hydrostatic pressure on the outer shell, weight of cargo load working on the bottom structure, ballast water pressure inducing the deformation of the ballast tank, etc. For instance, let's imagine a transverse section of a ship floating in still water as illustrated in Fig. 3. This section is subjected to (a) hydrostatic pressure due to surrounding water and (b) internal loading due to self-weight and cargo weight. These loads are not

Ship Structural Design,
Fig. 3 Example of deformation due to transverse strength loads (Yasuhisa Okumoto et al. 2009)

always equal to each other at every point, consequently loads working on transverse members will produce transverse distortion as shown by the broken line in Fig. 3.

- Local strength loads: The local strength loads, which include loads that affect the local strength members such as shell panels, stiffeners, and connecting constructions between stiffeners, is mainly the pressure acting on the shell plating and the load transmitted to the internal structure. The other important load is the wave slamming load, especially for the high-speed ship's crotch structure.

Strength Evaluation

The ship structure has been planned originally by the designer in such a way that the structure can effectively resist the presumed maximum load, which is estimated from previous experience of failure modes of damage. When the designer starts a ship structure design, the very first step is to establish the magnitude, direction, probability of occurrence of the load, and the structural failure modes experienced in the past.

- Determine an initial system of structural members.
- Presume a magnitude, direction, and probability of load.
- Assume a failure mode of structure due to the load.
- Select an appropriate analysis method.
- Choose acceptable strength criteria for a particular failure mode.
- Analyze structural response.
- Evaluate the response for given criteria.

Materials

Selection of materials is very important in structure design, because it directly affects ship cost and strength. Hence, the structure designer should know well the characteristics of materials, especially newly developed ones. Reasonable material selection should ensure the strength of the ship structure and reduce the weight of the ship as much as possible. For different materials, choose the appropriate welding method to ensure the service life. For special parts of ships and special

ships, materials with suitable properties should be selected.

Key Applications

Application History

With the growth in demand for ships and an increase in their complexity, ship structural design and calculation procedures have advanced considerably. Earlier, ships were designed and dimensioned solely on the basis of prescriptive rules from classification societies, which were themselves largely based on experience and feedback from ships in service; in the final quarter of the last century, rational analysis and design methods were introduced (Hughes et al. 2010).

The former Soviet Union first used the strength calculation design method in shipbuilding. In the 1950s, it issued the strength criteria including strength calculation conditions (external force, stress) and allowable stress standards, but the method still belongs to the deterministic design method of "analysis and verification."

Since the 1960s, the shipbuilding industry has undergone profound changes. The ship is required to be safer and more reliable, and at the same time, it must have higher efficiency and economy. Therefore, the old normative design method cannot adapt to the new situation, and it is urgent to establish a more scientific and versatile structural design method. In addition, due to the emergence of high-speed electronic computers, the finite element method of structural analysis and the optimization technology of mathematical programming have developed rapidly, which makes the structure design workers not only have a powerful fast calculation and analysis tool but also have a systematic method to improve juice design and optimize design. Just like the changes in the structural design fields such as aviation and civil architecture, the basic principles and methods of ship structural design are gradually undergoing profound changes.

Firstly, the structural design gradually transitions from a deterministic design principle to a probabilistic design principle. The so-called probability design method is reliability design. It is

based on the probability model of load and strength, which is to use various parameters that affect structural safety and performance during the life of the structure as random variables, using probability theory and combining statistical methods to analyze the probability that the structure meets the basic functional requirements during the service period. Many countries and international organizations have adopted new structural design standards and norms in some areas using structural reliability theory. In the field of ship engineering, the probability-based ship structure design is still in its infancy due to the complexity of the problems faced, but this far-reaching change is gradually deepening. According to the development stage and the degree of precision, the current international probabilistic design method is divided into three levels:

- **Full Probability Design Method:** This method is a design method based entirely on probability theory. It requires an accurate probability description of the joint occurrence of various basic variables that contribute to the structural response, as well as the accuracy of the failure range, in order to obtain a “precise” failure probability of the structural or structural component as a direct measure of reliability. This method is quite difficult in both theory and application, so it is still in the research stage.
- **Approximate Probability Design Method:** This method involves some approximate iterative computational processes, using probabilistic and mathematical statistics to approximate the failure probability of a structure or component. It is generally desirable to make the failure range ideal and usually to simplify the expression of the joint probability distribution of the variable. Today, this method has entered a practical stage and is gradually becoming the basis for the development of structural norms in many countries.
- **Semi-probability Design Method.** This method uses mathematical statistics analysis for certain quantities that affect structural safety and introduce some empirical coefficients in combination with experience, so it is also

called semi-probability semiempirical design method. This method does not estimate the reliability of the structure quantitatively. The appropriateness of structural reliability is provided on the basis of structural components (and sometimes on the basis of structures) by applying a number of subitem safety factors which are related to predetermined eigenvalues or standard values of the major variables of the structure and load.

In addition, with the wide application of electronic computers in structural analysis, the optimal design method characterized by “comprehensive and optimized structure” has rapidly developed. The structural optimization design not only reduces material consumption and cost under conditions of strength and stiffness but also enhances the function of the structure when needed. However, it is essentially a tool only, and it is impossible to solve the problems that are not solved by the structural design principle.

Finally, it is about the load state of the design and the form of damage to be prevented. The limit state calculation method is a major development in structural design. The former Soviet Union applied this method to some structural design specifications in the 1950s. Japan also applied this method in some ship construction specifications in the 1960s and 1970s. Today, the calculation of structural reliability and safety is inseparable from the limit state analysis.

Computer-Aided Design

Computer-aided design (CAD) is the process of creation and manipulation of design models on a computer to assist the engineer in the design and analysis process. In the modern environment, CAD can be used to design, simulate, develop, and optimize engineering structures.

Today, in ship structure design and analysis, it is possible to use the CAD model not only for visualization purposes but also for other analytical purposes such as basic structural form design, configurational design, design of final dimensions, simulation of motion characteristics, design of required plate sizes and thickness for

production, design of heating pattern for welding and joining, etc.

The complex beam structure is a 2D/3D structure subjected to simple or combined loading, e.g., superstructure comprising of side frames, deck frames, longitudinal girders, and compression posts that is subjected to deck pressure and sea pressure simultaneously, and this is analyzed for stress, deflection, and vibration. In ship structural analysis, normally three methods of analysis are employed, and they are (Sharma et al. 2012):

- Spreadsheet computation: The spreadsheet is used for the first set of local calculations to the class society rules. They can also be used for simple one-dimensional beam calculations as the formulas are quite straightforward and easy to write in a spreadsheet format.
- Beam modeling: A 1D beam such as a fixed-ended beam with a uniformly distributed load can be analyzed with a simple spreadsheet. However, 2D/3D models or 1D model with a complex load condition is analyzed with beam modeling software, e.g., deck beam of the mid-ship section.
- Finite element analysis: The beams in a ship are normally welded directly to the shell plate. This means that the shell plate is included in the beam properties. In this formulation, the results give an indication of the stress in the plate; however, due to the mathematical formulation of a beam element, the analysis does

not consider the connection of adjacent plates. Therefore to compute shell plate stresses and deflections, other methods are needed, e.g., finite element analysis (FEA).

Finite Element Method

FEM is a numerical solution method to discretize the continuum based on variation principle. It can disperse the hull structure into a finite number of units that can accurately simulate its load-bearing mode and deformation. The details of the hull structure can be described in detail. To express the coordination relationship and changes among various components, it is possible to determine the actual deformation and stress of each component or area. This method is currently the most accurate and perfect method for hull strength analysis, and it is also the structural analysis method that can accurately forecast the response of structures to loads in rational structural design. Figure 4 is an example of a finite element model of a medium-sized containership.

Our general-purpose finite element software includes ABAQUS, ANSYS, ADINA, SAP, MARC, NASTRAN, etc. The mainstream finite element software in the shipbuilding industry is NASTRAN. It has an open, fully modular organization structure that not only has strong analysis capabilities but also ensures good flexibility. Users can choose and combine the system requirements to get the best application system according to their own engineering problems. In addition to

Ship Structural Design, Fig. 4 Finite element model of a 9200 TEU containership (Hughes et al. 2010)

the universal finite element software, the world's major shipbuilding countries have developed ship-specific finite element software, such as the SHIPRIGHT system of the Lloyd's Register of Shipping, the SAFEHULL system of the American Classification Society, the NAUTICUS system of the Norwegian Classification Society and France, Classification Society's VERISTAR system, etc.

In general, depending on the requirements, the finite element analysis of the hull structure can be divided into the following three different levels:

- Analysis of the entire ship: The purpose is to obtain the overall situation of stress and deformation of the hull, which is mainly used for strength analysis of special ships such as large-opening vessels (such as container ships).
- Analysis of compartments: Evaluate longitudinal hull girder components, primary support members, and transverse bulkhead strength. The classification of the models is not exactly the same for each classification society based on their respective considerations.
- Subdivision mesh analysis: Evaluate the detailed stress levels of local structural details.

Example of New Ship Structure Design

In order to meet the needs of the market in terms of ship environmental protection, transportation economy, and maximum safety, Stena Bulk Shipping Company and other companies have jointly developed a product tanker E-MAXair with low emission, low energy consumption, and complete redundancy. The ship's design features include optimized hull structure (patented), the use of two large low-speed rotating propellers, and the use of LNG and special sails using wind to reduce fuel consumption. The ship uses airMAX technology to design a cavity that creates an "air cushion" on the bottom of the ship while using the newly developed ball nose to reduce hull resistance. Compared with ordinary oil tankers of the same scale, E-MAXair tanker significantly reduces energy consumption and emissions and improves transportation economy and ship safety. Optimization of ship structural design plays a key role in the development of new ship types.

In April 2010, the Norwegian Classification Society (DNV) launched the future environmentally friendly container concept ship "Quantum" (shown in Fig. 5). The main purpose is to reduce the negative impact on the environment by reducing fuel consumption while transporting more containers. When designing the "Quantum"

Ship Structural Design, Fig. 5 Future environmentally friendly container concept ship "Quantum" (<http://www.baidu.com/>)

Ship Structural Design,**Fig. 6** “River-to-SeaNo. 1” (<http://www.baidu.com/>)

container ship, DNV adopted a variety of techniques to improve the efficiency and environmental friendliness of the ship. In the hull design, the ship width is increased to improve stability and reduce the demand for ballast water. The ship uses an innovative wide deck design to increase the packing capacity and a narrow outboard side tank design to improve break stability and reduce steel weight. The ship obtains a smaller square factor (only 0.57) by optimizing the ship shape and the bulb nose and adopts an aerodynamic design of the wave breaker to reduce the wind resistance. For the main engine and propulsion, “Quantum” is equipped with four dual-fuel (marine diesel and LNG) generator sets to drive two pod-type electric propulsion units. Various improvements in the ship structure design have greatly improved the performance of this concept ship.

On April 10, 2018, “River-to-Sea No. 1” which is the first river-to-sea ship full of 20,000 t of iron ore sand in China (shown in Fig. 6) completed its first flight, marking the opening of a new era of China’s shipping industry. River-to-sea ship has the characteristics of both inland riverboats and seagoing vessels. Compared with traditional ships, river-to-sea ships have been innovative in terms of size, proportion, and configuration.

By improving the seagoing ship such as shortening the length and increasing the width of the seagoing ship, the river-to-sea can be obtained. Similarly, it is through the change of ship structure design that the river-to-sea ship structure can meet the requirements of sea and river transportation without intermediate transportation.

Synonyms

Fit out a ship; Fitting-out; Outfit; Outfitting

Definition

Ship-fitting design is defined as the installation work of all devices, facilities, and equipments besides the ship hull structure, including hull fitting, machinery fitting, electric fitting, power plant, control device, pipeline, etc. In the process of modern shipbuilding, the workload of fitting is 50–60% of total workload of shipbuilding. For the complicated ship, this percent will be higher. So the fitting is the indispensable component of shipbuilding (Fig. 1) (Liang 2011).

Scientific Fundamentals

Fitting Equipment

See Fig. 2.

The facilities used for ship fitting could be classified as (Wang 2013) anchoring equipment, mooring equipment, rudder equipment, evading equipment, hoisting equipment, lashing equipment, lifesaving equipment, fire accessories, close device, ladder pole equipment, accommodations, kitchen equipment, marine ventilator, flexible unit, etc. Each fitting facility also contains many equipment and accessory, as shown in Table 1.

Fitting Classification

Ship fitting can be classified as construction process as unit fitting, section fitting, block fitting, berth fitting, and wharf fitting. Also ship fitting can be classified as content as hull fitting, engine room fitting, and electric fitting. And hull fitting can be classified as inner fitting and outer fitting. Inner fitting is also called accommodation fitting, while outer fitting is also called deck fitting.

Classification According to the Construction Process

Fitting unit is defined as the fitting assembly containing a group of fitting equipment. Unit fitting is the work to assemble the fitting equipment in the unit into the fitting assembly of the fitting platform in the plant. The unit fitting is carried out at three stages. The stages are unit

Ship-Fitting Design,**Fig. 1** Fitting locale
(FreeImages.com/szymon
szymon)

installation on section, unit installation on block, and unit installation on inboard. For example, some deck machines in outer fitting, such as anchor gear, gangway ladder, radar mast, etc., are combined into a whole by unit fitting and then hoisting to deck for positioning installation. The fitting equipment can be divided into fitting unit including equipment unit, bin unit, valves unit, panel unit, etc. (Wang 2011).

Section or block fitting is carried out at a proper stage of section or block construction and installs the fitting equipment or fitting unit on the corresponding section or block. Section or block fitting regards the section or block as fitting area and is carried out at platform in infield or outfield as the order of intermediate product assembly. Compared to the berth fitting and wharf fitting, section fitting or block fitting improves the working environment and working posture. The high-altitude operation is changed to ground operation, and the production efficiency, installation quality, and work safety are enhanced; meanwhile the number of scaffold and fitting period is reduced (Wang 2011).

Unit fitting, section fitting, and block fitting are defined as advanced fitting, as shown in Fig. 3, and are the technology concept appeared since the fitting and hull construction should be alternated

or parallel according to the IHOPS and modern shipbuilding mode (Li and Liang 2007).

The berth fitting during berth final assembly and wharf fitting after launching all belong to inboard fitting. Ideal inboard fitting is limited to (1) the fitting equipment or fitting unit that is too large or too heavy to be installed on section or block; (2) the fitting equipment that is easy to be damaged before the compartment cover; (3) the fitting connecting piece between units and sections (Diao 2006). The fitting area of inboard fitting should be divided by the central position of fitting equipment, such as engine room area, rudder area, deck area, superstructure area, etc. Since the fitting workload is heavy and fitting period is long in engine room area, the inboard fitting should be started when the engine room open area is formed during ship assembly. By this way, the ventilation and lighting condition are well during the inboard fitting; meanwhile the installation into cabin for large equipment and fitting unit is more beneficial (Diao 2006; Wang 2011).

Classification According to Fitting Content

Engine room fitting is defined as the installation and trial run for all kinds of equipment in engine room. And the fitting work mainly contains the

Anchoring equipment
(FreeImages.com/Phillip Collier)

Close device

Life-saving equipment
(FreeImages.com/Andy Muir)

Ship-Fitting Design, Fig. 2 Classical fitting equipment

installation and trial run for engine room equipment and erecting welding for fitting equipment. The former contains the installation for large mechanical equipment such as main engine, shafting device, boiler, dynamo, etc. And the latter contains the installation for piping system, substrate, and bin in engine room. The characteristics of fitting in engine room are intensive equipment, high accuracy requirement, poor work condition, and inefficiency (Fig. 4) (Xu 2015).

Electrical fitting is defined as the installation, wiring, examine and trial run for electrical equipment, and cable laying. Compared to the electrical equipment with the same function on land, the working environment of electrical equipment on ship is worse. And the shockproof performance, moisture resistance, and anti-corrosion property

must be considered. So the structure of electrical equipment is more complex, and installation technology is different. Especially the marine cable, since its laying must be carried out in narrow space, its structure and laying are special. Now, the degree of marine electrification and automation is increased day by day, and the workload of electrical installation is multiplied. To speed up the process of electrical fitting, the technologies like preassemble and electrical lofting are generalized. The electrical fitting is divided into infield preparation and outfield preparation. The condition of infield preparation is well, and the hull work will not affect the infield preparation. So the infield condition can be started ahead of time. The condition of outfield preparation is bad, since the work is disperse and high above

Ship-Fitting Design, Table 1 Fitting equipment classification (Wang 2013)

Fitting facility categories	Fitting equipment and accessory
Anchoring equipment	Anchor, anchor cable, hawse pipe, anchor recess, anchor rack, anchor stopper, abandon the anchor device, chain cable fairlead, anchor davit
Mooring equipment	Mooring rope, mooring pipe, fairlead, mooring bollard, cable reel
Rudder equipment	Rudder blade, rudderstock, tiller, rudder carrier, neck bearing, steering wheel
Evading equipment	Spring towing hook, spring free towing hook, clevis joint, towing post, pneumatic spring
Hoisting equipment	Derrick boom, derrick bearing, lifting hook, chain and swivel, lifting tackle, eye plates and rings, shackle, funiculus, jack rope winch
Lashing equipment	Container fasteners, container binding, tank fixing device, automotive aircraft fixtures, quick screw
Lifesaving equipment	Lifeboat, rescue boat, life jacket, cork hoop, inflatable life raft, davit gear, lifting frame
Fire accessories	Fire bucket, water cage with box, sand and sand box, withdrawal tool
Close device	Door, windows, hatch cover, manhole cover
Ladder pole equipment	Ladder, handrail, storm rail, backdrop
Accommodations	Room furniture, sanitary ware, ironware
Kitchen equipment	Steamer, oven, dishwashing machine, boiling water device, kitchen multipurpose machine, dirt crusher
Marine ventilator	Ventilation head, ventilation opening, ventilated brake
Flexible unit	Turnbuckle, shackle, eye plates and rings

the ground faceup. The section fitting can improve the work condition and balance operating load. So the electrical fitting should carry through the principle “more infield work and more section work” (Li 2010).

The hull fitting can be divided into inner fitting and outer fitting. The inner fitting is also called accommodation fitting containing the laying of

insulation and dressing, non-steel wall, ceiling, door, windows, furniture, toilet, kitchen equipment, refrigeration house equipment, air condition equipment, etc. The outer fitting is also called deck fitting containing rudder and steering equipment, ground tackle, mooring equipment, towing equipment, life-saving equipment, cargo lift equipment, hatch cover, roll-on/roll-off facilities, firefighting accessory, natural ventilation accessory, pipeline, etc. The outer fitting is throughout the whole ship and covers the area except the engine room area and accommodation area. And the fitting equipment of the outer fitting to be assembled is numerous (Figs. 5 and 6) (Diao 2006).

Features of Fitting (Ying 2013)

In the whole productive process of fitting, it has the features including many aerial works, interchange works, over waterworks, and special works. It covers almost all kinds of shipbuilding. The main features are shown as below.

Many Aerial Works

With the development of shipbuilding industry, the size of ship hull is increased. At the inboard fitting stage, the whole ship has folded and undocked. So a large number of workplaces are far from the ground, so aerial works are everywhere in fitting (Fig. 7).

Many Interchange Works

At the fitting stage, the cross-operation of each department and occupation is taken place at the high, middle, and low place of the ship's hull and cabin. This situation will bring about the difficulty of interconnection and coordination for each occupation. And the accident happens at a high risk.

Many Restricted Space Works

For all kinds of ship, although they vary in size and their forms are different, they all have a set number of hermetic and narrow cabin. In the restricted space, the work is inconvenient, and high concentration of inflammable, explosive, and toxic substances may occur because of the poor ventilation condition. So explosions and poisoning accidents may happen at a high risk (Fig. 8).

Ship-Fitting Design, Fig. 3 Advanced fitting (Fang 2014)

**Ship-Fitting Design,
Fig. 4** Energy room fitting

S

Many Fire Operations

The fire operation including electrowelding and gas cutting is the main occupation of shipbuilding. According to the statistics, welding work always

accounts for more than half of the total time of ship hull construction. At the fitting stage, many fire operations often conduct simultaneously on the same ship (Fig. 9).

Ship-Fitting Design,**Fig. 8** Most energy rooms have restricted space works**Ship-Fitting Design,****Fig. 9** Fire operations
(FreeImages.com/Daniel Vazquez)**Many Dangerous Goods**

In the fitting, there are many dangerous goods, such as oxygen, propylene, and acetylene used for gas welding and cutting, marine paints, etc. These goods are all inflammable and explosive substances.

Many Occupations

Fitting needs numerous operating personnel, including productive work and service work. The productive work contains electrician, bench worker, burner, welder, assembler, plumber,

cabinetworker, painter, etc. The service work contains ventilate and illumination worker, lifting worker, scaffold worker, etc.

Key Applications

Since the development of manufacturing technology and design technology, the development stage of shipbuilding technology can be divided into (Wang 2013):

First stage, shipbuilding schema that is system oriented. In this stage, the main technologies are in bulk at slipway, wharf fitting, and coating the whole ship.

Second stage, shipbuilding schema that is system and region oriented. In this stage, the main technologies are section building, advanced fitting, and advanced coating.

Third stage, shipbuilding schema that is region, type, and stage oriented. In this stage, the main technologies are hull process lane construction, regional fitting, and regional coating.

Fourth stage, intermediate production-oriented shipbuilding schema. In this stage, the main fitting technology follows the hull construction fitting and painting integration schema (Okayama et al. 2006).

Fifth stage, production-oriented shipbuilding schema. In this stage, the fitting technology follows the integration schema of design and manufacturing.

The first stage and second stage belong to the traditional shipbuilding technology. The third stage and fourth stage belong to modern shipbuilding technology. The fifth stage is future shipbuilding technology (Wang 2013). As shown from the evolution of shipbuilding technology, the development process of fitting can be divided into the stages as follows: slipway and wharf fitting stage, advanced fitting stage, region fitting stage, hull construction fitting and painting integration stage, and hull and fitting separation stage. The hull and fitting separation technology is the development direction of modern shipbuilding schema and is the new construction technology improved from the fitting technology according to the modular technology (Calvo 1987; Baade et al. 1998; Jolliff 2010). The separate construction of hull and fitting can realize the fitting unitization and function modularization (Liu 2012). Besides the modularization, the fitting technology also shows tendency of the premiumising, environmental protection, and energy-saving (Wang 2013).

Modularization (Zhou 2008; Liu 2012)

The main advantages of the fitting modular design are forward production hour, less shipbuilding

cost, and improved work method and work environment (Zhou 2008).

The core of the modern shipbuilding is to realize the production rhythm with balance and continuity. With the shifting forward of production hour increasing, the period of dock and wharf will be reduced, and the use of radio as core resource is enhanced. As the analysis of statistics, if the same works are arranged at different construction stages, the engaged production hours of C stage, B stage, P stage, and D stage are 1, 3, 6, and 9, respectively (where C, B, P, and D mean the craft stage of little assemblage, large assemblage, slipway, and wharf, respectively). Thus it can be seen, since the bad work environment of the later stages with more aerial work and more preparation time of auxiliary facilities, the engaged production hour is increased obviously.

The engaged production hour of advanced shipyard is balanced. The engaged production hour of later stages is reduced; thus the total production hour is also decreased obviously. The fitting modularization can advance drastically the work at each stage mentioned above, and the construction hour is reduced obviously.

The fitting modularization design and manufacture can reduce the time and complexity of running and assurance in total life cycle including the design, construction, procurement, and so on, through the modularization, standardization, and process simplification of electromechanical devices. Thus the total cost in shipbuilding period and service period is also reduced. Meanwhile, the modular design and manufacture can advance the work at slipway to infield or outfield. It also reduces the cost, since the expense of unit or module installing in infield or outfield is five to seven times lower than that at slipway or dock.

The traditional shipbuilding industry is called 3K industry, i.e., dirty, laborious, and dangerous, and is labor-intensive industries. With the improvement of working method, the work environment can be improved as well. And the labor-intensive industries can be turned into equipment-intensive industries and knowledge-intensive industries. Through the modular shipbuilding including modular fitting, the spare parts have to

be installed in section, block, and dock before but now can be installed at open flat ground. It will improve the work environment obviously.

The shipbuilding modular can be divided into self-maintaining modular and attachment modular (Zhou 2008).

The self-maintaining modular is the advanced fitting unit on the section or block. It has independent substrate or support structure and can be prefabricated at infield and installed on the ship subsequently, such as CO₂ fire extinguishing device, remote control valve set for infusion system, seawater and freshwater pressure tank, ordinary crew accommodation, etc.

Attachment modular indicates that the design modular usually, since the wide arrangement range of its equipment and high requirement of fixation, is dependent on the structure of section or ship in the actual construction. The prefabricate of the attachment modular will be limited by the schedule of hull construction, but the optionality of equipment and universality of unit are the same with self-maintaining modular, so the attachment modular is also called as drawing shipbuilding modular.

In addition to the two modules mentioned above, there are many distributional fitting equipments on the ship. The distributional fitting equipment module is the particular case of attachment module, and it mainly contains the pipeline, cable, and its accessories.

The features of these modules are having independent function, impeccable port, well interchangeability, applicability, advancement, and commodity.

In the future, the fitting module will be developed in that direction of functionality, regionality, and integrity (Liu 2012).

Functionality module treats the equipment with strong independence as principal part, and has independent function, connecting with pipeline, accessory, electric appliance, iron fitting equipment, etc., to be a entirety. This type of module has well technology performance, convenient operation, and reliable quality, such as module of fuel oil, slide oil, and oil purifier, fuel feed module, cold and hot water pressure cylinder module, various kinds of individual oil tank, etc.

Regional module is the overall module with large scale and completeness and is an advanced fitting form with high production efficiency, quick returns, and good benefits, for example, the overall fitting module in dynamo region, in inner bottom of engine room region, in chimney region, etc.

Integrity module contains the radar mast, light mast and inert gas discharge column module, material shelf module, transport module, ventilating device module, system device module, etc.

Premiumising

Premiumising is mainly embodied at the appearance of fitting equipment, such as esthetic measure, symmetry, paint coat, design and manufacturing accuracy, etc., and the performance of fitting equipment, such as running smoothness, interface fit degree, interchangeability, etc. Although premiumising is the target of fitting development, excessive and one-sided pursuing of premiumising will increase the production costs too much. So the enterprise shall consider the actual situation and comprehensively consider the product competitiveness and economic benefits objectively (Wang 2013).

Environmental Protection and Energy Saving

Because of frequent human activities, the pollution of the sea is increasing day by day. So the environmental protection and energy-saving design for fitting equipment must be considered. At first, the material of fitting equipment must be nonhazardous and environmental, to reduce the pollution. Secondly, the energy of ship should be saved as much as possible. On the one hand, more manual operations can be added and, on the other hand, minimize the weight of the equipment to save the material and energy at the same time (Wang 2013).

Ship-Iceberg Interactions

Zhenhui Liu

Front End Engineering, Aker Solutions ASA,
Trondheim, Norway

Synonyms

Confinement; High-pressure zone; Iceberg;
Pressure-area relationship; Ship

Definition

Iceberg is formed from land-based glaciers by falling off from the land. It is made from

freshwater rather than sea water. The ship-iceberg collision is a potential hazard for those ships navigating in ice-covered areas. However, due to the increased technology of detection system on board, the probability of large iceberg colliding with ship might be marginal. **Ship-iceberg interactions** shall include the global and local effects of both ship and iceberg. Due to the existence of free surface, the complicated ice mechanic properties, this phenomenon is a complicated topic on ocean engineering.

Scientific Fundamentals

Iceberg Types

The iceberg can be categorized according to its main dimensions, the height over sea level (H) and the overall length at sea level (L), see Fig. 1. The draft of iceberg (D) is normally not known (Table 1). There are studies performing the statistic relationship between H , L , and D , see Fig. 1.

According to the shapes of iceberg above sea level, following six types are defined:

- (a) Tabular iceberg: a flat-topped iceberg, width is greater than five times height
- (b) Blocky iceberg: a flat-topped iceberg with steep sides
- (c) Domed iceberg: an iceberg with smooth and round top
- (d) Pinnacled iceberg: an iceberg has a central spires
- (e) Wedged iceberg: an iceberg with wedge shaped top
- (f) Drydocked iceberg: an iceberg which is eroded to a U-shaped slot

Type (a) and (b) are the main types for those new icebergs. The rest of the types are for those icebergs drifting in the ocean for a certain time (Fig. 2).

Global Ship-Iceberg Interaction

The study of ship and iceberg interaction is a complicated subject. One way to simplify the study is the split of external and internal mechanics as illustrated in Fig. 3. The external mechanics is about the global impact study. The hydrodynamic

Ship-Iceberg Interactions, Fig. 1 Main dimensions of iceberg

Ship-Iceberg Interactions, Table 1 Iceberg classification by size, based on Canada (2016)

Name	Height above sea level H (m)	Length L (m)	Weight W (Mt)
Growler	$H < 1$	$L < 5$	$W \approx 1.0 \text{ e}^{-3}$
Bergy bit	$1 \leq H < 5$	$5 \leq L < 15$	$W > 0.01$
Small berg	$5 \leq H \leq 15$	$15 \leq L \leq 60$	$W > 0.1$
Medium berg	$16 \leq H \leq 45$	$61 \leq L \leq 120$	$W \approx 2.0$
Large berg	$46 \leq H \leq 75$	$121 \leq L \leq 200$	$W \approx 10.0$
Very large berg	$H > 75$	$L > 200$	$W > 10.0$

effects, the eccentricity of both objects shall be considered in the assessment. The internal mechanics is the detailed study of the interaction between ship and iceberg at the impact area.

Liu and Amdahl (2010) further apply Stronge’s impact theory to study the ship and iceberg interaction. The governing equation is listed as follows:

$$dv_i = m_{ij}^{-1} dp_j \tag{1}$$

where dv_i is the relative velocity change on i direction, m_{ij}^{-1} is the inverse of inertia matrix, see Stronge (2004), dp_j is the impact impulse on i direction. The inverse inertia matrix is symmetric, i.e., $m_{ij}^{-1} = m_{ji}^{-1}$. The following are representative elements:

$$m_{11}^{-1} = (M^{-1} + r_2^2 I_{33}^{-1} - 2r_2 r_3 I_{23}^{-1} + r_3^2 I_{22}^{-1}) + (M'^{-1} + r_2'^2 I_{33}'^{-1} - 2r_2' r_3' I_{23}'^{-1} + r_3'^2 I_{22}'^{-1}) \tag{2}$$

$$m_{12}^{-1} = (M^{-1} + r_1 r_3 I_{23}^{-1} - r_3^2 I_{21}^{-1} - r_1 r_2 I_{33}^{-1} + r_2 r_3 I_{31}^{-1}) + (M'^{-1} + r_1' r_3' I_{23}'^{-1} - r_3'^2 I_{21}'^{-1} - r_1' r_2' I_{33}'^{-1} + r_2' r_3' I_{31}'^{-1}) \tag{3}$$

$$m_{13}^{-1} = (M^{-1} + r_1 r_2 I_{32}^{-1} - r_2^2 I_{31}^{-1} - r_1 r_3 I_{22}^{-1} + r_2 r_3 I_{21}^{-1}) + (M'^{-1} + r_1' r_2' I_{32}'^{-1} - r_2'^2 I_{31}'^{-1} - r_1' r_3' I_{22}'^{-1} + r_2' r_3' I_{21}'^{-1}) \tag{4}$$

where M^{-1} , M'^{-1} are the inverse of mass matrix for ship and iceberg, respectively. I_{ij}^{-1} , $I_{ij}'^{-1}$ are the inverse of inertia matrix for ship and iceberg, respectively. r_i , r_i' are the vectors from the center of gravity to the collision point for ship and iceberg, respectively. In these expressions, it should be noted that the matrix I_{ij} of moments and products of inertia has an inverse, which is denoted by I_{ij}^{-1} , e.g., $I_{21}^{-1} = (\hat{I}_{13}\hat{I}_{23} - \hat{I}_{12}\hat{I}_{33})/\det(\hat{I}_{ij})$. Recently, Liu and Amdahl (2019) presented the detailed

Ship-Iceberg Interactions, Fig. 2 Iceberg types based on the shape over sea level, photos provided by David Stanley, Lavivm, Andreas Weith, Magnus Manske, Natalie Lucier, and Kim Hansen, respectively

procedures on deriving the equation of motions for ship collisions. The formulation was presented under the ship's body coordinate system, rather than the local coordinate system at the impact point. By doing this, the items in the inertia matrix could be approached with the so-called reduction factors, which was first proposed by Popov et al. (1969) by considering the normal impact force only. It unifies existing ship impact theories, see Liu and Amdahl (2019) for more details.

As shown in Fig. 4, a local coordinate system is established at the collision point and the equations of motion are transformed to the local coordinate system. A transformation matrix is defined based on the ship's hull shapes, see Eq. (5).

$$T_{lg} = \begin{bmatrix} \cos(\alpha) & -\sin(\alpha) & 0 \\ -\sin(\alpha)\sin(\beta') & -\cos(\alpha)\sin(\beta') & -\cos(\beta') \\ \sin(\alpha)\cos(\beta') & \cos(\alpha)\cos(\beta') & -\sin(\beta') \end{bmatrix} \quad (5)$$

Ship-Iceberg Interactions,

Fig. 3 Illustration of external and internal mechanics (Liu et al. 2011)

Ship-Iceberg Interactions,

Fig. 4 Collision model by Liu and Amdahl (2010), with permission of Elsevier

where α , β' are the waterline angle and normal frame angle of ship, respectively at the collision point. The definition of angles can be found in DNV (2009).

The impulse in each direction, $\vec{n}_i$ ($i = 1, 2, 3$), is given by:

$$dp_i = f_i dt \quad (6)$$

where f_i is the i th component of the interaction force acting on the infinitesimally small deforming element in the $\vec{n}_i$ direction at the collision point.

The relative acceleration $\ddot{s}_i$ in each direction is:

$$\ddot{s}_i = \frac{dv_i}{dt} \quad (7)$$

By substitution of Eqs. (6) and (7) into Eq. (1), we obtain:

$$\ddot{s}_i = m_{ij}^{-1} f_j \quad (8)$$

The acceleration can be written as:

$$\ddot{s}_i = \frac{d\dot{s}_i}{ds_i} \frac{ds_i}{dt} \quad (9)$$

Substituting Eq. (9) into Eq. (8) and integrating over the impact duration t , it can be seen that:

$$\begin{aligned} \int_0^t m_{ij}^{-1} f_j ds_i &= \int_0^t \dot{s}_i d\dot{s}_i \\ &= \frac{1}{2} \left((v_i^t)^2 - (v_i^0)^2 \right) = \frac{1}{2} \Delta v_i^2 \end{aligned} \quad (10)$$

where v_i^t, v_i^0 are the relative velocities before and after the collision in the $\vec{n}_i$ -direction, and Δv_i^2 is the change of the squared relative velocities v_i^t and v_i^0 . Note that it is not always positive.

$$\Delta v_i^2 = (v_i^t)^2 - (v_i^0)^2 = dv_i(dv_i + 2v_i^0) \quad (11)$$

where dv_i is the relative velocity change in the $\vec{n}_i$ -direction:

$$dv_i = v_i^t - v_i^0 \quad (12)$$

Further,

$$\begin{aligned} \int_0^t m_{ij}^{-1} f_j ds_i &= m_{ij}^{-1} \frac{f_j}{f_i} \cdot \int_0^t f_i ds_i \\ &= E_i \cdot m_{ij}^{-1} \frac{f_j}{f_i} \end{aligned} \quad (13)$$

Substitution of Eq. (13) into Eq. (10) yields:

$$\begin{aligned} E_i &= abs \left(\int_0^t f_i ds_i \right) \\ &= \frac{1}{2} \cdot abs \left(\frac{1}{m_{ij}^{-1} \frac{f_j}{f_i}} \cdot \Delta v_i^2 \right) \end{aligned} \quad (14)$$

where “abs” indicates to calculate the absolute value because the force f_i and ds_i may be not at the same direction. If we define an equivalent mass variable $\bar{m}_i$ as follows:

$$\frac{1}{\bar{m}_i} = m_{ij}^{-1} \frac{f_j}{f_i} \quad (15)$$

Then, the dissipated energy has the following form:

$$E_i = \frac{1}{2} abs(\bar{m}_i \Delta v_i^2) \quad (16)$$

Equation (16) shows that the complicate *IDOF* can be simplified to a *IDOF* problem in each direction if the equivalent mass $\bar{m}_i$ and change of the squared relative velocity Δv_i^2 can be derived. These can only be done by introducing proper

Ship-Iceberg Interactions, Fig. 5 An example of ship and iceberg impact by Liu and Amdahl (2010), with permission of Elsevier

boundary conditions, such as the friction definition and relative velocities.

The final output of this method is the impact energy between ship and iceberg. An example case has been shown in Figs. 5 and 6. An iceberg with idealized shape collides with a tanker in its front area. As seen from Fig. 6, the energy dissipation ratio largely depends on the normal frame angle of ship. Comparing to the 2D method approach, the 3D approach is less conservative. The maximum energy dissipation happens for the normal frame angle between 20° and 30° in the studied case.

Local Ship-Iceberg Interaction

Mechanism

Iceberg ice falls within the category of a multi-year ice, which has survived at least two summer seasons. It is composed of freshwater ice from land-based glaciers flowing off the land into the sea. Iceberg ice can be idealized as an isotropic material, as it shows no significantly different mechanical properties in each direction (Sanderson 1988). In this sense, it is comparatively simpler than sea ice. However, iceberg ice is also influenced by temperature, porosity, grain size, strain rate, and confinement. In general, the

Ship-Iceberg Interactions, Fig. 6 Energy ratio and mass ratio relationship (Liu and Amdahl 2010), with permission of Elsevier

ice becomes weaker and softer with increasing temperature, porosity, and grain size. The effect of the strain rate (loading rate) was discussed by Schulson and Duval (2010). Strength increases with increasing strain rate until brittle failure takes over after which strength decreases. There exists a transition from ductile to brittle, with a strain rate of 10^{-3} . In iceberg collisions, it is believed that the strain rate is greater than the transition value, as discussed by Liu et al. (2011).

During a collision with structures, ice within the center contact area undergoes large confinement and compression (see Fig. 7). High-pressure zones (HPZ) exist in these areas, which may be as high as 70 MPa. For ice features next to the edge, spall and extrusion are more likely. A phase change from ice to water is possible in these small areas. Thus, for high hydrostatic pressures, the ability of ice to resist deviatoric stresses is reduced.

Numerical Simulation

A key technique in the numerical simulation of the ice-structure interactions is the choice of failure

criterion for ice, either plastic yielding or fracture initialization/propagation. Due to the large uncertainties on the ice properties, the failure criterion might be not straightforward to obtain. The material models for steel and soil are not suitable due to the independence of hydrostatic pressure on the material strength. This section presents an approach proposed by the authors, in which a shear-cap yield surface, so-called “Tsai-Wu” (e.g., Tsai and Wu 1971), is used to simulate iceberg impact behaviors.

The Tsai-Wu yield surface for isotropic material is usually written in the following form:

$$f(p, q) = q - \sqrt{a_0 + a_1 p + a_2 p^2} \quad (17)$$

where p is the hydrostatic pressure, $p = \frac{\sigma_{kk}}{3} = \frac{I_1}{3}$ and q is the deviatoric stress, $q = \frac{3}{2} \sqrt{s_{ij} : s_{ij}}$, s_{ij} are the deviatoric stress components, and a_0, a_1, a_2 are constants which should be fitted to triaxial experimental data. In order to make the implementation

Ship-Iceberg Interactions, Fig. 7 Schematic illustration of the ice and structure interaction by Jordaan (2001), with permission of Elsevier

convenient, the Tsai-Wu yield surface is rewritten in $p - J_2$ space as follows:

$$f(p, J_2) = J_2 - (a_0 + a_1 p + a_2 p^2) = 0 \quad (18)$$

where J_2 is the second invariant variable for deviatoric stress tensor, $J_2 = \frac{1}{2} s_{ij} : s_{ij}$. Figure 8 shows a comparison of the recommended inputs based on various data sources in $p - J_2$ space. It is seen that there are big differences existing which are due to the different data sources and the fitting methods used to approach the experimental data sets.

An empirical failure criterion, as follows, was proposed in the present doctoral thesis; see Eqs. (19) and (20).

$$\varepsilon_{eq}^p = \sqrt{\frac{2}{3} \varepsilon_{ij}^p : \varepsilon_{ij}^p} \quad (19)$$

$$\varepsilon_f = \varepsilon_0 + \left(\frac{p}{p_2} - 0.5 \right)^2 \quad (20)$$

where ε_{eq}^p is the equivalent plastic strain; ε_{ij}^p is the plastic strain tensor; ε_f is the failure strain; ε_0 is the initial failure strain, which should be adjusted

according to experimental data; and p_2 is the larger root of the yield function. If $\varepsilon_{eq}^p > \varepsilon_f$ or if the pressure is less than the cut-off pressure p_{cut} , erosion is activated. This failure criterion is based on trial-and-error and is purely empirical. Only one input parameter (ε_0) is needed (Fig. 9).

Present iceberg material model has been successfully applied to simulate the head-on collision between iceberg and ship. The simulation was carried out in the same environment as that used in the previous validations. Figure 10 shows that the strain energy was dissipated in both the iceberg and the ship structure for the bow collision with iceberg and rigid wall. In scenario A, the penetration distance corresponding to an energy dissipation of 18.2 MJ is 1.5 m; the ship structure undergoes minor plastic deformations while the iceberg dissipates most of the energy (Fig. 10a). In other words, the ship bow structure is strong enough to crush the iceberg. For scenario B, 75.5 MJ is dissipated for a penetration distance of 3.9 m. Both the ship bow and the iceberg experience large plastic deformations. Ice particles have been eroded extensively (Fig. 10b), and the bow is subjected to significant crushing behavior. It is interesting to see that there is a “maximum crushing distance” for the ship bow corresponding

Ship-Iceberg Interactions, Fig. 8 Illustration of Tsai-Wu yield surface in $p - J_2$ space from different sources, see Liu et al. (2011)

Ship-Iceberg Interactions, Fig. 9 Illustration of the failure criteria curve ($p_2 = 100 \text{ MPa}$), from Liu et al. (2011)

Ship-Iceberg

Interactions, Fig. 11 A full view of the numerical simulation model by Gagnon and Wang (2012), with permission of Elsevier

to the present ice material model. From this point, the bow structure begins to undergo significant permanent deformation (see the turning point symbol (☆) in Figs. 3, 4, 5, 6, 7, 8, 9, and 10). This takes place for a penetration of 1.7 m, which corresponds to an internal energy dissipation of 25 MJ. Using the results of the external mechanics calculations, the associated iceberg mass is estimated to be 1750 t. In other word, if the iceberg is heavier than 1750 t in the present scenario, the bow will be crushed. In future studies, a failure criterion will be included for the steel material so that tearing of the shell plating can be accounted for as well.

Complete Ship-Iceberg Interaction Simulation

Comparing to the methods mentioned above, an advanced approach could be also done by integrating the hydrodynamic, ice failure, and the ship structure failure together in the assessment. Figure 11 shows a complete model of a numerical simulation of ship and iceberg (Gagnon and Wang 2012). The drawback is that such approach is very time consuming and special knowledge to the numerical simulation tool is required.

Short Pile and Uplifting Capacity

Ting Huang¹ and Yinghui Tian²

²Department of Infrastructure Engineering, The University of Melbourne, Melbourne, VIC, Australia

Introduction

Offshore floating infrastructures, such as the traditional FPSOs and the emerging floating wind turbines, must be held in position to resist winds, waves, and currents in harsh environments. Anchor piles are a widely used type of foundations in offshore engineering to provide the required tensile load. For the new generation of renewable facilities which have relatively smaller dimension, short piles are often selected to resist the load passing through a catenary or taut wire mooring chain. Normally, uplifting load is imposed on the short piles.

These anchor piles have relatively larger stiffness with smaller embedment depth compared to the traditional piled foundation subjected to compressive load. Thus, short piles mostly behave as a rigid foundation and its deflection is usually negligible.

Various approaches are suggested to identify the short piles. Generally, there are two traditional categorizations. Bierschwale et al. (1981) pointed out that piles with L/d (embedded length/pile diameter) less than 6 could be considered as short (rigid) pile. Poulos and Davis (1980) proposed a criterion based on the elastic theory

analysis in the form of flexibility factor, K_r , which is given by

$$K_r = E_p I_p / E_s L^4 \quad (1)$$

where E_p is pile elastic modulus; I_p is inertia moment of pile cross section; E_s is elastic modulus of the surrounding soil. They suggested that if the flexibility factor is less than 10^{-5} , flexible pile behavior is expected, whereas if it is over 0.01, the pile will be fairly rigid.

Ultimate Capacity

Uplift Resistance

The shaft friction capacity in compression, Q_s , is calculated as local shaft friction at failure along the shaft of a pile, τ_f , and the depth, z , as:

$$Q_s = \pi d \cdot \int \tau_f dz \quad (2)$$

where τ_f is local shaft friction at failure along the shaft of a pile; z is depth. The uplifting capacity of piles consists of shaft friction and the weight of the pile. The pile capacity in tension, Q_u , is less than or equal to, but shall not exceed Q_s . In the previous design code, it is mostly considered that Q_u is equal to Q_s for the piles in clay. But for the piles in sand, a factor which is less than 1.0, e.g., 0.75 in UWA-05 (Lehane et al. 2007), is suggested. Furthermore, in computing the tensile uplifting capacity of the pile, the weight of the pile and the soil plug shall be considered. However, no difference is considered between long piles and short piles, basically. In the following content, some design formula for investigating shaft friction, τ_f , for piles in clay and sand are presented.

Chattopadhyay and Pise (1986a) provided a theoretical method for calculating the uplifting capacity of a circular vertical pile embedded in sand using limiting equilibrium. The failure surface is assumed curved and passing through the surrounding soil mass. The lateral horizontal extent of the failure surface is dependent on the friction angle of the surrounding soil, ϕ , interface friction angle, δ , and the slenderness ratio $\lambda = L/d$.

Short Pile and Uplifting Capacity, Fig. 1 Pile and failure surface (Chattopadhyay and Pise 1986a)

The axis system and configuration of the pile are shown in Fig. 1. During uplift loading, an axisymmetric solid body of revolution of soil along with the pile is assumed to be initiated to move up along the resulting surface. The movement is resisted by the mobilized shear strength of the soil along the failure surface and the weight of the soil and the pile. Some assumptions have been made. The lateral horizontal extent of the failure surface from the axis of the pile is maximum for $\delta = \phi$, and it gradually increases and keeps constant when δ increases to a particular value. For $\delta = 0^\circ$, the inclination of the failure surface with the horizontal at the ground surface approaches 90° .

With the pile and the proposed failure surface as shown in Fig. 1, it is assumed that the ultimate uplift capacity of the pile is attained in the limiting equilibrium condition, when the mobilized shear strength of the soil along the failure surface and the weights of the body of the soil and pile balance the applied uplift forces. A circular-disc wedge contained between the axisymmetric failure surfaces is considered, which is of thickness Δz at a height z above pile tip. The failure surfaces for different slenderness ratios are evaluated from the following equation, which was proposed by

$$\frac{X_G}{d} = \frac{1}{2} + \frac{\lambda \exp(-\beta)}{\beta^2 \tan\left(45 - \frac{\phi}{2}\right)} \left(1 - \frac{1}{\beta}\right) \quad (3)$$

where β is $(50 - \phi)/(2\delta)$. Eventually, net uplift capacity P_u (NET) is given by ϕ

$$P_u = A\gamma\pi dL^2 - \frac{\pi d^2}{4}\gamma L \quad (4)$$

where uplift capacity factor $A = \frac{1}{L} \cdot \int_0^L \times \left\{ \frac{2x}{d} \left(1 - \frac{z}{L}\right) (\cot \theta + (\cos \theta + K \sin \theta) \tan \phi) \right\}$; coefficient of lateral earth pressure, $K = (1 - \sin \phi) (\tan \delta / \tan \phi)$.

A similar study was presented by Faizi et al. (2015). A series of small-scale physical modelling tests were conducted to investigate the uplift resistance of piles in loose sand, and PIV was utilized to observe the bearing mechanism. Fig. 2 shows the displacement field derived from the PIV analysis in loose sand when the pile was at peak resistance, post-peak, and fully removed, and a complete deformation mechanism related to three bearing stages was presented. Peak resistance was associated with the formation of a sliding surface bounded by a pair of distributed dilating shear zones. Normality was not obeyed, so a limiting equilibrium method could better represent the failure mechanism than an upper bound strict plasticity. The infilling occurs with large downward displacement of the sand particles near the piles. As the soil closed the pile fell, the uplifting zone got narrower, and the uplifting zone was steeper sided. This flow-around mechanism with a maximum wide curve around the pile was mobilized at a displacement of almost the same embedment pile length.

An extended failure surface is widely accepted for the cases of pipes and flat anchors under uplifting (White et al. 2008). At present, this

Short Pile and Uplifting Capacity, Fig. 2 failure mechanism for piles by PIV method by particle movement at: (a) peak resistance; (b) flow around stage; (c) fully removing of pile. (Faizi et al. 2015)

failure mechanism is not popular for long piles yet. But for the short piles in sand, rough pile shaft with large interface friction angle, δ , can lead to a failure surface which forms inside the surrounding soil. Additionally, dilation induced by upward loading increases radial effective stress on the shaft and failure tends to happen in the distant soil with relatively low effective stress. In general, the bearing mechanism considering the extent failure surface is more applicable for short pile while calculation may be significantly conservative using traditional methods ignoring the slenderness ratio $\lambda = L/d$.

Inclined Tensile Resistance

Theoretically, the failure mechanism of the short pile under inclined tensile loading is more complex than a long pile. The anchor pile resists pullout as a combination of bending plus passive resistance and skin friction shear. A simplification of piles compared to shallow foundations is that

the interaction between combined loads is less significant: the application of a horizontal load does not significantly affect the vertical capacity and vice versa. This is because horizontal load is resisted over the upper few diameters of the pile (3–6 d), whereas vertical load is resisted on the lower part of the pile, where the stress and soil strength is generally higher. This conclusion is available for long piles. However, for short piles both lateral and axial pullout load components will interact. Skin friction will be reduced in the upper part of the pile due to the gap formation surrounding the pile during loading.

Additional insights into the interaction of short piles can be obtained from test results in the literature (Patra and Pise 2006; Kong et al. 2015). Fig. 3 shows the results of short piles in centrifuge tests (Huang et al. 2019). The experiments were conducted in a geotechnical centrifuge at 100 g using aluminum closed-end piles with length, $L = 155$ mm, diameter, $d = 22$ mm, wall

Short Pile and Uplifting Capacity, Fig. 3 Centrifuge tests for short piles: (a) Pile loading arrangement; (b) Variation of pile capacity; (c) Interaction of vertical and horizontal components (Huang et al. 2019)

thickness, $t = 4$ mm, and mass, $m_p = 136$ g. The surface of each pile was either anodized or bead blasted such that the piles could be categorized as either (almost) smooth or rough. A fine-to-medium subangular silica sand was used. The samples were first prepared by air pluviation with the piles “pre-located” in the container, before saturation from the sample base. An electrical actuator was used to load the piles, either in displacement control for monotonic loading. Loading was achieved using a steel wire that was connected to a point 12 mm above the pile head and the vertical axis of the actuator. Variations in the load inclination, θ (the angle of inclined load with the horizontal plane), were

achieved by presetting the vertical and horizontal distance between a pulley located at the base of the actuator and the pile head. Pile capacity was measured using a load cell located in series with the mooring line. A displacement rate of 0.1 mm/s was adopted for the monotonic tests. Capacity reduces as the load inclination becomes more vertical, reflecting the transition in failure mechanism from a combination of passive and active soil resistance along the pile under pure horizontal loading, to pure shearing at the pile-soil interface or inside the soil under vertical loading (Fig. 3b). The effect of interface roughness is most pronounced for load inclinations between $\theta = 90^\circ$ and 45° ; below 45° the difference in capacity

for the rough and smooth piles reduces from 15% at $\theta = 45^\circ$ to 5% at $\theta = 0^\circ$. Fig. 3c shows that as the load inclination reduces from $\theta = 90^\circ$ to 0° , the vertical capacity component initially reduces (at $\theta = 75^\circ$) and then increases up to $\theta = 60^\circ$ (rough pile) and $\theta = 45^\circ$ (smooth pile). When the load inclination further reduces, passive resistance is mobilized, leading to pile capacity increases that are more significant for the smooth pile than the rough pile. Fig. 3c also shows the theoretical interactions for the rough and smooth pile, assuming no coupling between the vertical and horizontal capacity components – that is, the shape of the interaction diagram is rectangular.

Experience of how piles perform under tensile, inclined loading from inclined taut moorings is much less. Previous experimental results indicate that the ultimate oblique pulling resistance is a continuous function of θ . Available approaches of inclined tensile capacity are dependent on its vertical and horizontal capacity. A semi-empirical method has been proposed by Chattopadhyay and Pise (1986b) to predict the ultimate inclined pulling resistance, P_θ , in terms of $m = P_u/P_l$ and θ .

$$P_\theta = P_u \cos^2 \theta \exp \left(- \left(\frac{1-m}{1+m} \right) \frac{90-\theta}{90} \right) + P_l \sin \theta \exp \left(- \left(\frac{1-m}{1+m} \right) \frac{\theta}{45} \right) \quad (5)$$

where $P_u = P_{\theta=90}$ is net ultimate uplift load for axial pulling; $P_l = P_{\theta=0}$ is ultimate resistance for horizontal pulling.

An alternative method was suggested by Meyerhof (1973), which applied an approximate parabolic interaction relationship between the limits of vertical and horizontal pulling resistance, P_u , and P_l , respectively.

$$\frac{P_\theta \sin \theta}{P_u} + \left(\frac{P_\theta \cos \theta}{P_l} \right)^2 = 1 \quad (6)$$

Key Applications

The main types of floating offshore platforms are tension leg platform, SPAR platform, semi-submersible platform, and Floating production,

storage and offloading platforms (FPSOs), marine energy converters, etc. Short piles, which are short and stubby, with a large diameter, are more popular for the facilities like FPSOs, wind turbines, and wave energy converters (WECs). In shallow water, a length of the anchor chain will rest on the seabed during calm conditions, with the small mooring loads being resisted by friction against the seabed. In deep water, a taut line mooring is common, with the mooring line angled at 35° to the horizontal or steeper.

Fig. 4 shows the illustrations of typical anchor pile moorings. The chain may be connected to the anchor pile at the soil surface, or it may be connected via an embedded pad eye, which provides a more efficient arrangement and inclined tensile load. For suction caissons with lower L/d than short piles, the pad eye location is in the range 0.1–0.75 L indicated by Houlsby and Byrne 2005. The alternative method for pad eye depth is according to moment equilibrium assuming no rotation under lateral loading to achieve the maximum lateral load carrying capacity.

A novel arrangement of short piles for WECs (Gaudin et al. 2017) is shown in Fig. 5. The avoidance of the extreme load on floating body may be achieved by adopting different strategies. The extreme load can be by mechanically lowering the floating body in the water, or survived by incorporating a fuse in the primary mooring. The fuse disconnects the device from the primary mooring line on time, and then the extreme mooring line loads transfers to a number of secondary moorings. When the WEC is producing power under normal operating conditions, WEC motion produces extension of the power take off, creating a cyclic mooring line force that is transferred to the foundation. WEC foundations are also required to withstand the loading associated with extreme events, during which the WEC will not be producing power, but is in “survival mode.” One option for dealing with the extreme loading event for such a mooring configuration is the use of secondary slack moorings. When the primary mooring is disconnected during extreme loads, the extreme loads acting on the WEC are then shared across a number of secondary moorings that are connected to adjacent foundations. In

Short Pile and Uplifting Capacity, Fig. 4 Anchor piles in mooring systems (Randolph and Gourvenec 2011)

Short Pile and Uplifting Capacity, Fig. 5 Mooring configurations for point absorber WECs (Gaudin et al. 2017)

this arrangement, short piles are supposed to subject vertical or inclined tensile load.

Some similar ideas, such as anchor sharing, as shown in Fig. 6, were proposed to promote anchor efficiency for both floating wind turbines (Breton and Moe 2009) and wave energy converters (Gao and Moan 2009). Herduin et al. (2018) indicated that the main benefit was lesser number of the required anchors. Fig. 7 and Table 1 show several “anchor efficient” array configurations for 3 point, 4 point, and 5 point mooring systems. As evident from Table 1, the array (a) is using the least number of anchors and therefore provides the greatest potential for cost savings from a

geotechnical perspective. The arrangement represented in Fig. 7c with a 5-point mooring system makes the array arrangement less efficient in terms of anchor’s numbers. Each of the array arrangements implies that the anchors are connected and loaded by one to six mooring lines. The individual load passed by mooring is multidirectional. Unlike the drag anchors whose bearing planes are kept normal to the loading orientation, short piles show the better applicability for resisting multidirectional loading. However, the loading applied to the short piles is complex. Fig. 8 shows the variety of loading configurations. θ_F is the phase angle of the wave

arriving adjacent three floating body. As the phase difference between the three loads varies from 0 to π , resultant contours transform from a thin ellipse suggesting nearly bidirectional loading to a circle centered at the origin indicating constant amplitude and large variation in direction. This variety is much more complex when consideration is given to irregular waves and wave direction.

Definition

Simultaneous localization and mapping (SLAM) is a technology of constructing or updating a map of an unknown environment through computational method while simultaneously keeping track of a robot's location within it. In recent years, SLAM technology has achieved great success in the field of underwater robot navigation and positioning. It enables underwater robots to explore and navigate in unknown marine environments; generate their own maps for the environment; be able to identify their location, landmarks, and obstacles; and make decisions based on the received new environmental data.

Scientific Fundamentals

Navigation and positioning are critical to the safety and effectiveness of underwater vehicle operations. The unavailability of the global satellite positioning system (GPS) has made underwater robotic navigation a challenging technical issue. In recent years, the performance of sensors applied to underwater vehicles has greatly improved, and the cost and size of these sensor devices have been greatly reduced. With the development of these technologies, advances in algorithms such as simultaneous positioning and mapping and collaborative navigation have greatly improved the navigation capabilities of

underwater vehicles. These improvements in underwater robotic navigation have contributed to the successful deployment of underwater vehicles in a variety of applications. Techniques have been introduced in finding a suitable technique to solve challenges faced by underwater vehicles as mentioned above. The aim is to improve and optimize the underwater vehicle performance in terms of landmark estimation, posterior and location estimation, effective path planning, and reduction of error made by the vehicle. When simultaneous localization and mapping (SLAM) are introduced, it became the most recognized technique by researchers (Leonard and Durrant-Whyte 1991; Paull et al. 2013).

Evolution of SLAM

In the decades since SLAM technology was introduced into the field of underwater robots, SLAM technology has been widely used. The development of SLAM has continued to this day to improve the efficiency and quality of SLAM algorithms in terms of accuracy, estimation, and reduction of error rates.

Durrant-Whyte (1986) had introduced the concept of implementing the estimation of spatial uncertainty at the IEEE Robotics and Automation Conference in San Francisco. Smith et al. (1987) had described a representation for spatial relationships which makes explicit their inherent uncertainty. Their researches are considered the starting point for the pre-development of SLAM technology. Leonard and Durrant-Whyte (1991) developed the SLAM technique based on the previous work using the probabilistic approach in solving the SLAM problem. That paper systematically introduces the implementation of extended Kalman filtering method.

In order to improve the efficiency of the SLAM algorithm, Montemerlo et al. (2002) introduced the famous FastSLAM algorithm. This SLAM algorithm is one of the most recognized SLAM methods after EKF-SLAM. The idea of FastSLAM is to use a hybrid method that integrates the particle filter and extended Kalman filter methods together. This implementation makes FastSLAM a high data accuracy and is therefore welcome. FastSLAM continued to

evolve and eventually formed the second version of FastSLAM, called FastSLAM 2.0. The modification made in FastSLAM 2.0 is that the distribution of proposals must rely on both the previous pose estimation and the actual measurement of the mobile robot, while the first version of FastSLAM only relied on the previous pose estimation of the mobile robot (Montemerlo et al. 2003).

Dellaert and Kaess (2006) proposed the smoothing method called square-root smoothing and mapping (SAM) for the improvement of the mapping process of mobile robots. The technique uses the square-root information smoothing approach in solving the SLAM problem in improving mapping process efficiency. Kim et al. (2007) introduce a new technique that provides a robust algorithm based on a scale unscented transformation called UFastSLAM. The technique proposed to improve the FastSLAM method by using the scale unscented transformation algorithm approach.

SLAM algorithm keeps improving and enhanced its reliability from the first introduced SLAM algorithm until recent SLAM development. Different SLAM algorithms try to tackle and improvise different aspects of SLAM problems. The ultimate objective in the SLAM algorithm is to realize the challenge of optimum navigation, localization, and mapping, that is, the capability of underwater robots to self-explore with no human interference in dynamic environments given a time period. SLAM development shows that numerous implementations have been applied to SLAM to deal with the more dynamic environment and multiple vehicle navigation (Khairuddin et al. 2015).

Mathematical Model for SLAM

The goal of SLAM is to make vehicles generate a relatively consistent environment map and use the generated map to estimate landmarks and vehicle positions at the same time. An important fact of SLAM is that it does not require any prior knowledge of mobile robots and landmark locations, as platform trajectories and landmark locations are estimated and calculated online. Suppose the vehicle explores the entire unknown environment and uses sensor devices

Simultaneous Localization and Mapping, Fig. 1 The basic implementation of feature-based SLAM (Khairuddin et al. 2015)

to observe and estimate the location of landmarks in the environment. Figures 1 and 2 show the basic implementation of feature-based SLAM.

In Fig. 1, both the robot and landmarks' location are estimated simultaneously, and the true robot and landmarks' location are unknown and not measured. Observations done are between true robot and landmark locations. The following variables are defined at time k .

- x_k Robot location
- X_k Sequence of robot location or path
- u_k Odometry between time $k-1$ and k
- U_k Sequence of robot odometry or relative motion
- m_i Map comprised of landmarks, objects, surfaces, and their respective locations
- Z_k Sequence of measurements between robot and landmarks assuming one measurement per time step

It is not appropriate to rely only on robot odometry U_k to determine robot location within a plane because, in the real application, it suffers the lack of precision required for accurate localization. Taking into consideration, the robot not

Simultaneous Localization and Mapping, Fig. 2 The basic implementation of view-based SLAM (Paull et al. 2013)

only can depend on odometry measurement alone but also relies on continuous sensory measurement Z_k for more accurate true location estimation. Once all the required information is obtained and defined, the next steps are building a map view of the environment and location prediction. SLAM technique is using the

probabilistic approach which applies a probability distribution to predict the robot and landmarks' location from the generated map. The probability distribution form, P , is defined as:

$$P(x_k, m | Z_k, U_k)$$

The above formula can be interpreted as the probability of the position at time k , and the map is drawn based on the history of the measurement and odometer data. The observation model of the robot can identify the relationship between the robot position x_k and the ranging u_k , which is defined as:

$$P(x_k | x_k, u_k)$$

Motion model of the robot identifies the relationship between sensory measurements z_k , map environment m , and robot position x_k which is defined as:

$$P(z_k | x_k, m)$$

In general application, the robot is able to detect landmark range, relative direction, and the unique identity in the typical environment. These understandings can be used as a basis to derive a measurement model. By applying probability distribution into the measurement model, it can be defined as:

$$P(z_k | x_k, m) \tilde{N}(h(x_k, m), Q_k)$$

where $h(x_k, m)$ is an arbitrary function that represents sensory equipment operation and Q_k is two-dimensional noise covariance.

For the motion model, a normal distribution is applied which focuses on kinematic motion model covariance. The motion model derivation is defined as:

$$P(x_k | x_k, u_k) = N(g(x_{k-1}, u_k), R_k)$$

where $g(x_{k-1}, u_k)$ is standard kinematic function and R_k is a three-dimensional noise covariance.

The robot will update its position and landmark measurement at the previous time step $k-1$ with

improved precision from the data it gathers from other landmark and previous robot position at time step k . The process is done continuously to update the robot measurement until the robot finishes its exploration in the environment (Khairuddin et al. 2015).

Filtering Approaches to SLAM

SLAM filtering methods use state estimation algorithms such as EKF-SLAM. Some methods use a combination of multiple filtering methods. The following sections describe some of the most popular SLAM method categories and their advantages and disadvantages.

EKF-SLAM

It uses Taylor expansion to linearize the system model. It applies recursive prediction-update cycles to estimate poses and maps. Its state vector includes poses and features. It applies to view-based SLAM and function-based SLAM. For large maps, since the calculation time is directly proportional to the number of features, EKF-SLAM is computationally intensive (Eustice et al. 2006).

SEIF-SLAM

Sparse extended information filter (SEIF) and precise sparse extended information filter (ESEIF) are two well-known methods of SLAM using information filters. They all maintain a sparse information matrix and therefore maintain the consistency of the Gaussian distribution. However, accessing the mean and covariance requires a large matrix inversion that is computationally intensive. Both methods need to actively “sparsify” the information matrix through a refinement strategy. ESEIF maintains an information matrix where most of the elements happen to be zero (Walter et al. 2007).

FastSLAM

It is based on a particle filter. The particle filtering method is a nonlinear filtering solution. Therefore, the system model is not approximate. In FastSLAM, poses and features are represented by particles (points) in the state space. FastSLAM is the only solution that can perform online SLAM and full SLAM simultaneously, which means that

it can estimate not only the current pose but also the entire trajectory. In FastSLAM, each particle contains poses and estimates for all features. However, each function is represented and updated by a separate EKF. Similar to other methods, it applies to view-based SLAM and feature-based SLAM (Montemerlo et al. 2002).

GraphSLAM

In the GraphSLAM method, the entire trajectory and map will be estimated. GraphSLAM also uses Taylor expansion for approximation, but it differs from EKF-SLAM in that it accumulates information and is therefore considered an offline algorithm. Generally, in GraphSLAM, the pose of a robot is represented as a node in the graph. Model the edges of connected nodes using motion and observation constraints. These constraints need to be optimized to calculate the spatial distribution of nodes and their uncertainty. For GraphSLAM, there are different solutions, such as slack on the grid, multilevel relaxation, iterative alignment, square-root smoothing and mapping, incremental smoothing and mapping, and hierarchical optimization of pose maps on the manifold. In principle, they are all similar, but optimization is implemented differently (Paull et al. 2013).

Artificial Intelligence SLAM

These methods of SLAM are based on fuzzy logic and neural networks. RatSLAM is a technique for modeling rodent brains using neural networks

(Wyeth and Milford 2009). In practice, this method uses a camera and an odometer for neural network-based data fusion. Saeedi et al. (2011) use self-organizing maps to perform SLAM with multiple robots. A self-organizing graph is a neural network that is trained without supervision.

Key Applications of SLAM in Underwater Vehicles

In traditional navigation methods, it is not possible to determine when the AUV will automatically locate without localization support for ships or sound transponders. With dead reckoning (DR) using inertial measurement units, the AUV increases its position based on knowledge of its direction and speed or acceleration vector. Traditional DR is not considered as the main navigation means, but modern navigation systems that rely on DR are widely used in AUVs. The disadvantage of DR is that errors are cumulative. Therefore, the AUV position error increases infinitely with the travel distance.

In recent years, through the development of underwater camera and sonar technology, underwater robots have gained more abundant marine environment information, as shown in Fig. 3. Therefore, underwater robot navigation technology based on sonar and visible light images has developed rapidly. Almost all methods in this category that implement boundary position errors use some form of SLAM.

Simultaneous Localization and Mapping, Fig. 3 Sonar sensor swaths: (a) side-scanning, (b) multi-beam, (c) forward-looking, (d) mechanical scanning and imaging, and (e) synthetic aperture (Paull et al. 2013)

Optical-Based SLAM

The visual ranging method is a process of determining the pose of the robot by analyzing subsequent camera images. This can be achieved by moving the optical flow or structure (SFM). Invariant extraction and representation of features is an important consideration. Many previous algorithms have been proposed and applied to ground and aerial robotics, such as scale-invariant feature transform (SIFT), accelerated robust features (SURF), etc. Images can be captured using a stereo or monocular camera. Another advantage of a stereo camera is that a full six-degree-of-freedom transform can be found between successive pairs of images. The main challenge is to close the loop in the trajectory by associating discontinuous images, which is necessary to limit the positioning error. Limitations of optical systems in underwater environments include reduced camera range, sensitivity to scattering, and insufficient light. Therefore, visible-wavelength cameras are usually mounted on hovering AUVs because they can approach objects of interest. In addition, visual odometers and feature extraction depend on the presence of features. Therefore, the underwater optical navigation method is particularly suitable for small-scale map drawing in a feature-rich environment.

Eustice et al. (2008) proposed the implementation of SLAM based on underwater vision, called visually enhanced navigation (VAN). The multi-sensor method combines the advantages of optical and inertial navigation methods and is robust to the low overlap of images. This method is a view-based version of EKF-SLAM, where camera-derived relative attitude measurements provide spatial constraints for visual ranging and closed loop. The VAN method is transformed into an information form and proves that view-based ESEIF-SLAM maintains a sparse information matrix without approximations or pruning (Eustice et al. 2008). This method has been applied to the deepwater measurement of Titanic. It also solves the problem of recovering the mean and covariance from the information table. Hover et al. (2012) use contour sonar and monocular camera functions. Hover the AUV for

hull inspection by using functions expressed using full sonar and monocular camera functions. Use the DVL locked on board to get the odometer relative to the hull.

Sonar-Based SLAM

By using acoustic detection technology, the underwater vehicle could identify and classify the features that can be used as navigation landmarks in the environment. With detection sonar, features can be extracted almost directly from the combined echo. The sonars used on underwater robots mainly include (a) side-scanning, (b) multi-beam, (c) forward-looking, (d) mechanical scanning and imaging, and (e) synthetic aperture. The following section uses the side-scanning sonar and ranging sonar as examples to introduce the related SLAM methods.

Side-Scanning Sonar

The image of a side-scan sonar is shown in Fig. 3 (a). The intensity of the sound waves returned by the fan beam from the ocean floor also depends on the type of the ocean floor and is recorded in a series of cross-track slices. When subdivided along the direction of travel, these assembled slices form an image of the seafloor within the beam. Hard objects protruding from the seafloor echo strongly and are represented by dark images. Shadows and soft areas (such as dust and sand) have weak echoes, represented by bright images.

Ruiz et al. (2004) have presented the SLAM method with the side-scanning sonar using an augmented EKF and the Rauch-Tung-Striebel smoother. The value of smoothing in the pose estimation is emphasized since all previous poses should be updated when a loop closure event is detected. It is noted that automated feature detection (which is not trivial) and data association are necessary to achieve autonomy for side-scanning sonar SLAM. Aulinas et al. (2011) have approached the SLAM problem by using a submap joining algorithm called the selective submap joining SLAM. Their work used a cascaded Haar classifier for object detection from side-scanning sonar imagery and is demonstrated offline on a gathered data set.

Ranging Sonar

Figure 3 (b) shows the multi-beam sensor image. Instead of using multiple beams to point a single transducer down, multiple beams in a transducer array are aligned on the AUV hull in a precise pattern. The sound bounced off the seafloor at different angles and was received by the AUV at slightly different times. The signal is then processed on the AUV, converted to water depth, and arranged as a sounding map. The multi-beam resolution achieved depends on its sensor quality, operating frequency, and height from the seafloor. Multi-beam sounding systems are often used to map large areas of the seafloor. Each measurement line traversed by the AUV collects a data channel called a strip. Multi-beam sonars produce 2.5-dimensional detection features (elevation maps), while side-scanning sonars produce 2-dimensional images.

Barkby et al. (2012) have proposed a bathymetric SLAM algorithm called BPSLAM that is based on a featureless FastSLAM implementation. In their approach, the need for feature extraction is removed, and each particle maintains an estimate of the current vehicle state and the 2-D bathymetric map. An important issue with employing a particle filter-based system with such a large state space is the computational expense of copying particles' maps during the resampling process. This problem is solved by "distributed particle mapping" where a particle ancestry tree is maintained. Copying of particle maps is avoided by having new particles generated during the resampling process point to their parents' maps rather than copying them. Maps of leaf nodes in the tree are reconstructed by recombining the maps of all ancestors. The need to store each particle's map is removed completely by storing just the particle's trajectory and linking poses to an entry in a log of bathymetry observations. Maps are then reconstructed as needed using Gaussian process regression, and, as a result, loop closures can be achieved even in the case where there is little or no overlap between sonar images since the regression process is able to make predictions about areas of seabed that have not been directly observed (Paull et al. 2013).

Heilongjiang, China

Synonyms

Catenary anchor leg mooring; Catenary mooring; Mooring system; Single point mooring; Taut mooring

Definition

The single anchor leg mooring (SALM) is a specific type of single point mooring (SPM) which is anchored by a tensioned leg to a base on the sea floor. A hose system and a fluid swivel concentric with the anchor leg permit cargo to

flow between the moored tanker and an underwater pipeline, while the tanker swings around the mooring (Flory et al. 1972; Luo 2015) (Fig. 1).

Scientific Fundamentals

System Composition

The mooring buoy is normally steel and has typical dimensions of 4 m diameter and 12 m height. Vessels are moored to the SALM by one or more hawsers connected to the mooring buoy (ABS 2014). Hawsers are normally made from synthetic fibers with dimension depending on tanker size and local operating conditions (SBM 2012). The SALM anchoring system has two main sections, the base and the anchor leg or riser (API RP 2SK 2005). The base is the principal structural member which secures the SALM in position. The single anchor leg is usually a large chain with a swivel incorporated to allow buoy rotation and prevent chain torquing. A fluid swivel is mounted concentrically about the anchor leg either on top of the base or on top of a riser. The fluid swivel permits the passage of fluid while rotating in response to the moored vessels movement. The hose strings for the SALM extended the fluid swivel unit to the moored tanker manifold and are composed of submarine and floating hoses. (Baritrop 1998).

SALM prevents collision damage to the swivels by placing them underwater and below the keel level of the tanker. Any damage should then only affect the simple surface buoy and be relatively cheap to repair (Gruy 1977).

Historical Development

The advent of very large oil tankers in the mid 1960s resulted in a need for new concepts in tanker terminals. Standard Oil of New Jersey affiliates, including Esso Standard Libya, were faced with requirements for expanding their facilities to accommodate tankers of 200,000 dwt and larger. Since the first set of SPM was used in the Arabian Gulf in 1964, various types of SPM have appeared one after another. In 1966, Esso Research and Engineering (ERE) began a research program to develop new single

Single Anchor Leg Mooring, Fig. 1 SALM (API RP 2SK)

point moorings. At about the same time, Esso Standard Libya requested that ERE investigate the feasibility of a new mooring concept, the single anchor leg mooring (SALM), for installation at their port at Brega, Libya. A second SALM was installed at Okinawa in 1971. Experience with these facilities has demonstrated the SALM to be a very successful design. Studies have shown the SALM offers considerable investment savings compared to conventional single point moorings in water depths greater than about 100 ft. Safety and reliability are other principal advantages (Vryhof Anchor Manual 2005).

Key Technology in the Development of SALM

After the concept of SALM system was proposed in 1966, the research on SALM system has been developing rapidly.

Butenin (1965) first proposed an approximate formula for the mooring lines in a SPM system. The shear strain effect based on the nonlinear elastic theory was added to the formula. At the same time, the anchor cables and pipes in the SPM system are considered as cantilever beam with very small stiffness coefficient. The results

show that when the nonlinear part is small, the results obtained by Butenin method are in good agreement with those obtained by other numerical methods.

Sarpkaya (1976) studied the influences of Re and roughness coefficient K on resistance coefficient CD (also known as drag coefficient) and mass coefficient CM systematically and drew the curves of the relationship between Re , K , CD , and CM of cylinders of different cross-section shapes in current. Labbe et al. (1983) analyzed the effects of different hydrodynamic parameters CD and CM on riser's response; proposed CD , CM , and Re are related to wave-period coefficient KC . The results show that the dynamic response of riser is insensitive to CD and CM in most cases, so the dynamic response of riser can be calculated by using CD and CM based on maximum Re and maximum KC .

Ansari and Khan (1996) did a systematic analysis of the influence of mooring line loads on ships. Halliwell (1988) uses line element to analyze the stress of anchor mooring cable in deepwater by incremental method and compiled

a geometric nonlinear finite element analysis program. Ahmad and Datta (1989) calculated and analyzed the dynamic response of riser components of offshore oil floating production platform under wave, current, and ship motion. Halliwell and Harris (1988) used model tests to study the effects of environmental and mooring system parameters on the mooring response. Hearn and Thomas (1991) compared four numerical integration methods for dynamic analysis of mooring systems – central difference method, Newmark method, Wilson- θ method, and Houbolt method, and it is found that Wilson- θ method has shorter calculation time and smoother numerical solution, which is more suitable for dynamic simulation of mooring system.

Ma Rujian and Li Guixi (1995) studied the nonlinear response of a SPM system in stochastic waves by using nonlinear spectrum analysis method.

Bin Pan et al. (1995) proposed a static calculation method for SALM system in a stable position under the action of external forces. Zhili Zou et al. (2002) studied the motion response, mooring force and fender collision force of mooring ship on oil platform under loads of wind, wave, and current. Based on the calculation results, the effects of different water levels and different angles between wind, wave, and current on mooring force and collision force were discussed (Fig. 2).

Key Applications

SALM system is usually used for shuttle tanker and FSO instead of FPSO. SALM can work in cooperation with semi-submersible drilling ships, and the prefabricated SALM can be used for supply ship transportation, installation, displacement, and positioning of vessels of various tonnage. It can be adapted to a wide range of weather conditions and water depths. It is quick and economical to construct and install, and it is suitable for retrofitted tankers (Luo 2015). The water depth of SALM reaches 500 m, deeper than CALM.

This system employs a vertical riser system that has a large amount of buoyancy near the surface, and sometimes on the surface, which is held by a pre-tensioned riser (GL 2014). The vertical buoyancy force acting on the top of the riser functions as an inverted pendulum. When the system is displaced to the side, the pendulum action tends to restore the riser to the vertical position. The tanker can be secured to the top of this SALM buoy with either a flexible hawser or a rigid yoke (Luo 2015). The base of the riser is usually attached through a U-joint to a piled or deadweight concrete or steel structure on the sea floor. In deepwater, the riser system usually has mid-span articulation.

There are two kinds of applications of SALM: one is SALM without riser and the other is SALM with riser.

Single Anchor Leg Mooring, Fig. 2 Single anchor leg mooring (SALM) with tubular riser and yoke

1. Single Anchor Leg Mooring (SALM) Without Riser

The pipe line does not pass through the buoy but combines the underwater oil hose with the surface floating hose into a hose. The system is anchored to the seabed and can withstand positive buoyancy and maximum mooring load. The installation depth of the system without riser is shallow, ranging from 20 m to 50 m, for example, the SALM system in Okinawa, Japan (Marcello et al. 1980).

2. SALM with Chain Riser

In order to increase the water depth, the number of SALM system installations with riser project has increased gradually. Different from the former, steel pipe called the riser is inserted between the anchor and the anchor chain. For instance, the installed SALM system with riser was installed in thistle oilfield in North Sea. It is 162 m deep; the riser's diameter is 2.5 m and the length is 101 m (Foolen and Smulders 1977).

As offshore activities continue to expand into the deep sea, the SALM system with riser has been put into use on a large scale. Figure 2 is the water depth and structure of several SALM systems, which was put into use from 1969 to 1981 (Marcello et al. 1980; Robert et al. 1980; Mack et al. 1981).

At present, the offshore oil industry is gradually developing into deeper waters in Gulf of Mexico, Brazil, western Africa, the north Atlantic, and the Norwegian Sea, with water depth in the range of 1000–3000 m. The operating depth of the production platform in Gulf of Mexico has exceeded 3000 m.

Definition

The passive mooring is the most commonly adapted station keeping method for offshore floating facilities. An offshore mooring system usually consists of one or multiple mooring lines that connect the floater to the seabed to retain floater's position and limit offset to enable designated operations in various environments and water depths. According to mooring system's control of floater heading, the mooring system can be divided into two main categories: **spread mooring system** (Fig. 1) and **Single-point mooring system** (Fig. 2). The spread mooring system utilizes spread mooring lines connected to the multiple locations of the floater to restraint its position as well as heading. The single-point mooring system has all mooring lines connecting to the point of rotation of the floater such that it only restrains the floater position while allowing floater weather

vanning. For both types of mooring systems, the mooring line is usually made up of chain, wire rope, polyester, anchor, and connectors. The mooring lines are pretensioned to form catenary or taut leg profile and spread out in all directions.

Historical Development

The mooring system can trace its origin to navigation. As ships sail around the world, the

anchor mooring hold vessel's position relative to a point on the seabed of a waterway without connecting the vessel to shore. As such, mooring lines have been used for station-keeping of floating vessels in various situations. For example, they are used to berth boats or ships at quaysides and often referred to as quayside moorings. In association with the development of offshore oil and gas exploration, the spread mooring system was further developed for station keeping of various offshore platforms for

operations of drilling, production, pipelaying, workover, etc.

When the ship shaped Floating Production Storage and Offloading system (FPSO) was first introduced, due to the challenges of spread mooring for ship-shaped FPSOs with excessive lateral load, the single-point mooring system was then developed. At present, most of the existing FPSOs are positioned with single-point mooring systems, and the spread moored FPSOs only exist in benign environment areas such as the West of Africa. A single-point mooring system allows the FPSO to freely rotate around a single point under the weather vane effect, thereby effectively reducing the forces of wind, waves, and current, so that the dimensions of the mooring systems are correspondingly reduced.

The world's first single-point mooring system was born in 1959 and was owned by the Royal Swedish Navy. The application of the single-point mooring system to the FPSO began in the 1970s. In fact, the vigorous development of FPSO and its mooring system were within the proceeding decade. At present, around 150 FPSOs are deployed in various sea areas of the North Sea, West Africa, South America, and Asia, most of which use single-point mooring systems (Nutter, 2014). The development of the global FPSO mooring system has generally gone through five phases, namely (Veldman, 1997; Ma et al., 2019):

- From 1976 to 1985, for the early stages of development, it became possible to deploy FPSOs in all areas for offshore oil and gas production through the single-point mooring system.
- From 1986 to 1994, during the FPSO growth period, the FPSO mooring technology was rapidly developed at this stage, associated with the increase of FPSO units by an average of two or more per year.
- From 1995 to 1998, during the expansion period of FPSOs, the number of FPSOs in this phase increased significantly, increasing at an average rate of more than 8 units per year.
- From 1999 to the present, the number of FPSOs has increased rapidly, and technological breakthroughs have been achieved. The

operating water depth increased from shallow water to 3000 m. The current record of FPSO operating water depth is Shell's Stone FPSO in the US Gulf of Mexico in a water depth of 2920 m.

- Especially after 2002, the FPSO concept has been extended to other types of operations such as in the form of LPGFPSO, LNGFPSO, Floating Storage and Regasification Unit (FSRU), Floating Production Drilling Storage and Offloading system (FPDSO).

The single-point mooring system is technically challenging and expensive to build. At present, companies that have the state of the art single-point mooring system technology are SBM, Bluewater in the Netherlands, SOFEC in the United States, and NOV (formally APL) in Norway and the United States.

Principles of Single-Point Mooring

Working Principle

The magnitude and directionality of the prevailing environment of the wind, waves, and current are the driving parameters of mooring system configuration. They dictate the selection of mooring system type, i.e. the spread mooring or the single-point mooring. FPSOs have large size often with an overall length of longer than 300 m. The traditional spread mooring system fails to perform because of excessively large lateral force in harsh environment areas. For FPSOs in harsh environments, the single-point moorings have to be selected.

The beauty of the single-point mooring system allows the FPSO to freely rotate around a center of rotation such that the FPSO heads towards the prevailing environment. To achieve the feature of free weather vanning, the FPSO is fitted with a facility called turret at the forward part of the hull. The turret is geo-stationary connected by one or multiple mooring lines to the seabed, and the FPSO is connected to the turret via bearings which allows the free rotation (Fig. 3).

The FPSO single-point mooring system together with the turret has three functions:

Single-Point Mooring, Fig. 3 FPSO Single-Point Mooring Schematics (Courtesy of SOFEC)

Single-Point Mooring,
Fig. 4 Working principle
of spread mooring system

1. Stationkeeping – the FPSO is kept in position at the offshore oilfield operation site by the mooring restoring force generated by the single-point mooring.
2. Transfer of liquid and power – through the special liquid swivel, electric slip ring, etc., the produced liquid, liquid injection to wells, electrical power supply, and communication signals can be continuously transmitted from seabed to FPSO or FPSO to wells while the FPSO weather vanes around the single-point mooring.
3. Disconnectability – for specially designed single-point mooring, the mooring system can be disconnected in extreme condition for the safety of FPSO and onboard personnel.

Mooring Design

Like the spread mooring system, under the environmental loading of wind, waves, and current, the FPSO offsets from its mean equilibrium position in the horizontal plane. As the floater offset increases, larger tensions are being generated among the windward lines and tensions on leeward lines reduce (see Fig. 4 for illustration). The imbalance of mooring forces generates a so-called mooring restoring force that counterbalances the environmental forces. The larger the offset, the bigger the mooring restoring force until the acting environment force is balanced by the mooring restoring force. In this way, the offset of the floater is

also kept within the design limit (Barltrop, 1998; Luo, 2013).

The magnitude of the environmental loads also dictates the size of the mooring system components which are designed to withstand the environmental loading complying to applicable design codes.

Mooring Components

Like the spread mooring system, the mooring line is typically made up of synthetic fiber rope, wire and chain or a combination of the three. In some cases, buoyancy modules as well as clump weights can be deployed along the mooring line to achieve specific objectives such as seabed clearance, more desired mooring performance, etc. Environmental factors – wind, waves, and currents – drive the selection of mooring line materials (Figs. 5, 6, 7, 8, and 9).

Offloading

The single-point mooring system is beneficial to the crude offloading. The shuttle tanker can be connected with the FPSO either in tandem or side by side with the tandem mode being the most popular. The shuttle tanker and the FPSO can rotate freely around the single-point mooring, and the offloading operation is convenient, safe, and reliable (Fig. 10).

Key Applications

In a broad term, the single-point mooring system consists of the turret and mooring lines. The turret is typically a cylindrical steel structure that

connects to the seabed via moorings and connects to the FPSO via rotation free bearings. The FPSO rotates around the inner bearings of the turret in countering the wind, waves, and current action. The mooring lines connect to the chain table which is at the bottom of the turret structure (Fig. 11) (Wichers, 2013).

There are different types of single-point mooring systems. The exact structural design of the turret system varies according to project specific requirements, hull size, environmental conditions, etc. According to different working characteristics and the location of the turret, the turret system can usually be divided into two main types: (i) internal turret system and (ii) external turret system.

Single-Point Mooring, Fig. 5 Studlink and studless chain (Courtesy of AsAc)

Single-Point Mooring,**Fig. 7** Multistrand wire rope (Courtesy of Bridon)**Single-Point Mooring,****Fig. 8** Polyester rope (Courtesy Lankhost)**Internal Turret System**

Among the mooring systems for FPSOs, the internal turret system is most commonly used in the harsh environments with large number of risers and umbilicals (Fig. 12). The internal turret is generally located near the bow of the FPSO, and the turret sits inside a moonpool of the FPSO hull. The mooring lines is connected at the bottom of the turret via chain table, and the flexible risers from the seabed are connected with the rigid pipes inside the turret, or directly connected upwards to the upper part of the turret.

The main features of the internal turret system include:

1. The turret diameter can be larger than that of an external turret system, providing plenty of space for a large number of risers.

2. The inner turret is well protected by the hull.
3. The presence of the turret reduces the tank capacity and has an impact on the hull structure.

External Turret System

The external turret system (Fig. 13) is similar to the inner turret system except that the turret is located outside the FPSO hull. The external turret system is frequently used in shallow waters say below 50 m to increase the effective water depth because the external turret is positioned well above the waterline.

The main features of an external turret system include:

1. It allows stand-alone fabrication and installation along the quayside, while the internal turret system can only be installed in the dry dock.

Single-Point Mooring, Fig. 9 Various types of anchors (Courtesy of Vryhof Anchor)

Single-Point Mooring, Fig. 10 FPSO in Offloading Operation (Courtesy of Bluewater)

2. It does not affect the storage capacity of the hull.
3. The mooring and riser connections are above water that eases the effort of inspection and maintenance.

Other Types of Single-Point Mooring Systems

To suit various types of operating environment and functionality requirements, other types of

Single-Point Mooring,**Fig. 11** Turret chain table
(Courtesy of SBM)**Single-Point Mooring,****Fig. 12** Internal turret mooring system in an FPSO
(Courtesy of SOFEC)

single-point mooring systems have been developed.

Tower Yoke Mooring System

The tower yoke mooring system uses a rigid jacket structure piled to the seabed as the anchor point and the FPSO is connected to the jacket via jointed steel members. The system was developed for shallow to ultra-shallow water (below 50 m) application where the conventional catenary mooring system fails to operate due to shallow water depth (Fig. 14).

Catenary Anchor Leg Mooring System (CALM)

With the growing crude oil trade, petroleum products are transported around the world. For coast area, the application of catenary anchor leg mooring system (CALM, Fig. 15) is preferred. CALM systems are used for temporary mooring of crude shuttle tankers for the purpose of loading and unloading of crude products.

The CALM system consists of a floating buoy moored by typically six spread mooring lines, and the turntable which is mounted on top of the buoy

for free rotation around the bearings. Like an FPSO, the shuttle tanker can weather vane to interact with the prevailing wind, waves, and current.

Size Effect and High-Pressure Zone of Sea Ice

Xue Long¹, Shewen Liu¹ and Shunying Ji²

¹Nava Architecture and Ocean Engineering College, Dalian Maritime University, Dalian, China

²State Key Laboratory of Structural Analysis for Industrial Equipment, Dalian University of Technology, Dalian, China

Introduction

In the physical mechanical test of sea ice, it is found that the strength of sea ice is not only related to the temperature, salinity, and other generating environment, but also closely related to the size of sea ice. By establishing the relationship between sea ice strength and size, the size effect of sea ice has been studied.

In the early research on ice load of offshore platform structure and ship structure in ice area, it is found that sea ice not only affects the overall stability of the structure, but also causes local damage to the structure. The problem of determining these “local pressures” is a long-standing one which has faced the designers of ships and offshore structures throughout the history of operations in ice covered waters. Local loads affect areas from 1 m² up to as much as 100 m² and determine the design of steel plate thicknesses plus spacing and size of bracing or concrete wall thicknesses and the amount of reinforcing (Masterson and Frederking 1993).

Definition

The *size effect* refers to the effect of material size on its mechanical properties. Size effect exists in many materials such as rock, concrete, ceramics, metal. Sea ice is a typical brittle material composed of crystal, which also has obvious size effect. The effect of sea ice size on its strength can be divided into two aspects, including the size

effect of ice specimens and the size effect of ice grain.

The *high-pressure zone* is the area of stress concentration caused by the nonsimultaneous destruction of the sea ice acting on the structure. A large number of measurement data and model tests show that the maximum local ice pressure of sea ice is much higher than the global ice pressure of the structure. Therefore, the high-pressure zones during the interaction of sea ice and structure may cause local deformation and damage of the structure, which will seriously threaten the stability of the whole structure.

Scientific Fundamentals

Ice Crystal Types

The crystal type and size of both sea ice and fresh water ice also have a great influence on the strength. Ice with different crystal types has different physical and mechanical properties. There are 13 crystal types of naturally formed ice. Previous studies have pointed out that ice is composed of hexagonal crystal, but due to the different growth environment and meteorological conditions, the texture characteristics of ice interior and the orientation of single grain in polycrystal are different. Therefore, ice with different crystal structure is formed. The crystal structure characteristics of sea ice mainly include grain shape, grain size, and its spatial distribution. The ice type can be defined according to the distribution characteristics of ice crystals, among which granular ice and columnar ice are most common shown in Fig. 1. The sea ice sheet has a two-layer structure: a granular ice layer on top and a columnar ice layer below. The granular ice is composed of particle grains with similar size, whose size is usually less than 10⁻² m. It is randomly arranged in space and has the characteristics of isotropic material. For columnar ice, the crystals are slender in the vertical direction (i.e., the growth direction of ice), while in the horizontal plane, the grains are closely arranged together. Its particle size ranges from 10⁻² m to 10⁻¹ m, and it has the characteristics of anisotropic materials. Hence, the columnar ice has significant anisotropy because of its

Size Effect and High-Pressure Zone of Sea Ice, Fig. 1 Different shape of ice crystal: (a) Granular ice and, (b) Columnar ice

columnar structure (i.e., the grain size in the vertical direction is larger than that in the horizontal direction). It mainly shows that the loading direction has an effect on its mechanical strength, while the grain size has no significant effect on its strength. Because of the diversity of crystal structure and grain size in ice, the influence of grain size should be considered according to different crystal types when determining the compressive strength of ice.

Global and Local Pressures

The ice pressure of structure can be divided into global ice pressure and local ice pressure. Figure 2 shows the definitions used for global and local pressures by the example of a cylindrical structure (Timco and Sudom 2013).

Global pressure is related to the global (or nominal) area, which is defined as the contact area that develops during the interaction. This is simply the area of the structure projected onto the dimensions of the ice feature at the appropriate amount of penetration. The size of this area could be small (e.g., laboratory tests), intermediate, or large (e.g., interaction of an ice sheet with an offshore structure). Global pressures are generally thought of with respect to overall structure design and stability. The global interaction area corresponds to the full area over which the ice exerts a force on a structure at a given moment in time during the process of a pressure-area interaction. The global ice pressure is the ratio of the ice load of

structure to the area of the whole contact surface, which represents the stress state of the whole structure. The area of contact surface can be equivalent to the product of structure width and ice thickness.

Local pressure occurs over a smaller, defined portion of a larger global area. For example, a local pressure could be captured on one instrumented pressure panel on the side of a large offshore structure. In this case, the pressure is generally calculated using the maximum ice load on the local measurement area during an event and the assumed corresponding local contact area. The local pressure is related to a part of the area of a structure to be designed; for example, a panel or the plating between frames. Because the area is inside a larger area of ice, its confinement conditions can be quite different than that for the global pressure. The high-pressure zones are the area of stress concentration caused by the non-simultaneous destruction of the sea ice acting on the structure.

Historical Development

Specimen Size Effect on the Strength

Generally, in the mechanical property test of materials, the size effect of material specimen can be divided into two kinds: the ratio effect between height and width and volume effect. Because of the transverse friction between the end face of the specimen and the indenter during the loading process, the ratio of the height and width of the

Size Effect and High-Pressure Zone of Sea Ice, Fig. 2 Grain size effect on the compressive strength of ice (Cole 1985)

specimen may affect the test strength. The other is the volume effect proposed for brittle failure. Under the condition of similar specimen composition, the larger its volume is, the more defects it contains and the greater probability of brittle failure is, so the test strength becomes lower.

In the compression test of sea ice, it is also found that the compression strength decreases with the increase of specimen volume. Sea ice is a compound material composed of pure ice crystal, brine, bubble, and other impurities. Hence, there are many defects in sea ice, which lead to that the composition of sea ice is more complex and the strength is lower than that of fresh water ice. When the internal defects of sea ice reach a certain degree, it is easy to form large salt discharge channels, and finally form cracks with different sizes in

different positions of the specimen. When the size of ice specimen is larger, there will be more defects inside the ice and the strength of ice specimen in the test will decrease. Kuehn et al. (1993) found that specimen size only has an influence on ice brittle failures and does not affect the ductile compressive peak strength according to the test results on the compressive strength of fresh water ice. In addition, the size effect of sea ice is also related to the material properties of compression test platens. When the strength is measured using superior platens, the size does not affect the brittle compressive strength. Specimen size does affect the brittle compressive failure strength when measured by using inferior platens, owing most probably to the effects of nonsimultaneity of failure in large specimens and of end-confinement in small specimens.

In this case, the strength decreases as the specimen size increases.

The tensile strength of ice decreases with increasing test specimen volume as shown in Fig. 3. Volume effects on the strength of brittle materials are usually described by a Weibull statistical distribution approach (Weibull 1951). The Weibull theory is often referred to as a “weakest-link” theory of fracture. In the Weibull theory, the probability of fracture is given by:

$$P = 1 - \exp(-v(\sigma/\sigma_0)^m) \quad (1)$$

where P is probability of fracture, σ is the applied tensile stress (which is assumed to be uniform over the stressed volume of the material), σ_0 is a constant, v is stressed volume, and m is the Weibull modulus. This expression leads to the following expression for the volume dependence of the strength of brittle materials:

$$\sigma_2/\sigma_1 = (v_1/v_2)^{1/m} \quad (2)$$

where σ_1 and σ_2 are the compressive failure strengths of specimens; v_1 and v_2 are the volume of specimens, respectively.

From the strength-volume data in Fig. 3, it was possible to obtain a Weibull modulus value for ice. The Weibull modulus of ice is estimated to

have a value of approximately 5. To our knowledge, this is the first time a Weibull modulus for ice has ever been put forward. By way of comparison, the Weibull modulus of brittle ceramic materials is typically in the range of 5 ~ 20. The higher the value of the Weibull modulus, the lower is the statistical scatter in the measured fracture stress.

Grain Size Effect on the Strength

Many scholars have studied the influence of grain size on ice strength through experiments, mainly for the granular ice. Cole (1985) conducted experiments on fresh water ice to analyze the effect of grain size on the internal crushing characteristics of polycrystalline ice. Meanwhile, the law of the compressive strength of ice changing with the grain size under different strain rates is summarized, as shown in Fig. 4. Schulson (1990) took the granular ice samples with different grain size as the research object and found that the brittle strength of ice is directly proportional to the square root of grain diameter, but it is only suitable for the brittle failure of ice. Found that the compressive strength of fresh water ice increased with the decrease of particle size. Jones and Chew (1983) found that when the size of the specimen must be more than 12 times of the grain size, the grain size has no effect on the strength; and when the grain size is between 0.6 and 2.0 mm, the

Size Effect and High-Pressure Zone of Sea Ice,
Fig. 3 Illustration of the global and local pressures (Timco and Sudom 2013)

Size Effect and High-Pressure Zone of Sea Ice, Fig. 4 Tensile strength of ice as a function of volume (Petrovic 2003)

compressive strength is not significantly affected by the grain size. When the specimen size is the same, the ice specimen with small particle size has larger uniaxial compressive strength, which can be explained by dislocation theory (Schulson 1999). For the same material, the smaller the grain diameter is, the more the grain boundary will be, which will hinder the dislocation movement. Therefore, materials with smaller grains need higher deformation resistance, and macroscopically, the materials have higher strength. On the other hand, a possible process is the propagation of microcracks that are nucleated by dislocation pile-ups against grain boundaries.

Compared with granular ice, the columnar ice has significant anisotropy because of its columnar structure (i.e., the grain size in the vertical direction is larger than that in the horizontal direction). It mainly shows that the loading direction has an effect on its mechanical strength, while the grain size has no significant effect on its strength.

Generation and Distribution of High-Pressure Zones

As we all know, the ice load estimation is required in the design of ships and offshore structures for arctic and subarctic conditions. With the development of research on the structural strength of ice regions, the ice pressure is also important to improve the appropriate levels of structural strengthening. When the overall stiffness of the structure meets the design requirements of ice load, the local damage of the structure may still occur. For example, in the process of ship structure navigation, the collision of sea ice can cause local deformation or even damage to the hull. Therefore, people pay more attention to the generation, size, and distribution of ice pressure.

A lot of researches have been made on the physical process of sea ice crushing by means of field tests and observations. The causes and distribution of structural high-pressure zones are analyzed considering the influence of sea ice failure mode, as shown in Fig. 5 (Jordaan 2001). When the sea ice interacts with the vertical structure, the

Size Effect and High-Pressure Zone of Sea Ice, Fig. 5 Schematic illustration of the main processes of spalling, extrusion, and high-pressure zone formation (Jordaan 2001)

upper and lower surface of the sea ice near the contact surface first crush. The broken sea ice is pushed out of the contact surface by the subsequent ice sheet. At the same time, the ice in the middle layer of the ice sheet has not yet broken, which forms a bulge and keeps interaction with the structure. Because of the continuous contact between the middle layer of ice sheet and the structure, the structure can form stable high-pressure zones. With the increase of ice load, the sea ice in the high-pressure zone will also be broken. The microcracks inside the sea ice gradually increase and continue to expand, and some larger ice blocks on the upper and lower surface will peel off again, and finally the sea ice will form a new bulge in the middle of the ice sheet. Therefore, the sea ice can cause continuous ice load on the structure, and the high-pressure zone of the structure also exists all the time.

According to the failure process of sea ice, the high-pressure zone mostly occurs near the center line of the contact surface and has a linear distribution, which is called “line-like load” (Jordaan et al. 2010). From the formation of high-pressure zones, the distribution of high-pressure zones is closely related to the failure mode of sea ice. Frederking (2004) analyzed an event for which an indenter of dimensions 1.5 m wide and 0.5 m high penetrated a sea ice sheet of 168 mm thickness at a rate of 3 mm/s, for a total penetration of 1000 mm. The entire indenter face was covered with tactile sensor elements which allowed direct observation of the pressure distribution during the indentation process. Figure 6 clearly shows that the pressure is certainly not uniform across the loaded indenter face. There is a “line-like” load along the center line of the indenter and two other regions of high-pressure zones along the top and bottom of the indenter

S

Size Effect and High-Pressure Zone of Sea Ice, Fig. 6 Distribution of high-pressure zones with crushing failure of sea ice: (a) the JOIA project in Japan; (b) view of

the pressure distribution on the face of the indenter in the JOIA tests analyzed by Frederking (2004)

face. This pressure distribution continually changed during the loading process but often resembled that shown in. Moreover, when the sea ice occurs the brittle crushing failure, the line-like distribution characteristics of the high-pressure zones on the vertical structure are hardly affected by the structural size and ice thickness, that is, it is independent of the size of the contact surface between the sea ice and the structure (Erceg et al. 2015).

Influence Factors of High-Pressure Zones

There is a strong perception in the ice mechanics community that during ice-structure interaction, the ice pressure always decreases as the area of contact increases. This understanding is often based on the pressure-area plot published by Sanderson (1988), which combines a large number of data sources and ice interaction situations on a single plot and shows a definite decrease in pressure with increasing area. The exponential fitting of the relationship between the local ice pressure and the contact area is widely recognized. Masterson and Frederking (1993) compiled a large

number of pressure-area points based on small- and medium-scale experiments, icebreaker impacts with ice, and larger-scale ice interactions with structures. In their analysis, local pressures were combined with global pressures measured over a smaller area. This combined data shows decreasing pressure with area with a functional form $p = 8.1A^{-0.572}$ for areas up to 19 m^2 , where p is the pressure (in MPa) and A is the area in m^2 . Above 19 m^2 , the pressure appears constant at $p = 1.5 \text{ MPa}$. Masterson et al. (Masterson et al. 2007) combined data from the MEDOF panels on the Molikpaq offshore platform, medium-scale field indenter tests and some flat jack tests to produce a combined pressure-area plot for local pressures. The data also showed a definite trend of decreasing pressure with increasing area, as shown in Fig. 7. Note that in contrast to the Masterson and Frederking (1993) plot, the Masterson et al. (Masterson et al. 2007) plot does not contain any data on ships in ice or global pressure-area data. The resulting upper bound pressure-area relationship for areas from 0.1 m^2 to 10 m^2 is given by $p = 7.4A^{-0.7}$. For areas greater

Size Effect and High-Pressure Zone of Sea Ice, Fig. 7 Local pressure-area relationship for fixed structures (Masterson et al. 2007)

than 10 m², the pressure is given as a constant 1.48 MPa. The ISO 19906 Arctic Structures Standard (ISO 2010) has adopted the Masterson et al. (Masterson et al. 2007) approach to provide guidance on measured pressures over specific local areas.

In addition, the law of ice pressure decreasing with the increase of contact area is not always unaffected. It will be changed by other loading environmental factors, such as loading rate, ratio of structural width to ice thickness, failure mode of sea ice and sea ice strength, etc. More importantly, the research shows that in some cases, these factors have more obvious influence on local ice pressure than the contact area (Timco and Sudom 2013). Sodhi (2001) pointed out the influence of loading rate on the failure mode and pressure distribution of sea ice. When the sea ice is loaded at low speed, it will have ductile deformation, and the ice pressure will increase with the increase of speed, and distribute on the whole contact surface; on the contrary, the sea will have continuous brittle failure under high-speed loading, and the ice pressure will decrease with the increase of ice speed, and concentrate on the center line of the contact surface. When the thickness of ice sheet increases, due to the change of sea ice failure mode, the distribution of local ice pressure is no longer concentrated in the middle line, and there may be multiple high-pressure zones (Jordaan 2001). Therefore, the value and distribution of structural ice pressure are closely related to the failure mode of sea ice. However, the research methods of high-pressure zone are mainly field or laboratory tests, so it is difficult to study the internal micro fracture characteristics of sea ice and the internal mechanism of high-pressure zones.

According to the research on the influencing factors of ice pressure, the Sanderson pressure-area plot is a mixture of vastly different data sources. As such, it is of interest in a general sense but is not meant to be applied for many specific situations. For specific applications such as structure or ship design, it is important to use a subset of only the appropriate data to define the most suitable pressure-area relationship. In doing so, other factors can be taken into account

including aspect ratio, loading rate, failure mode, and the physical and mechanical properties of the ice. In many cases, these factors are far more important than the area in defining the pressure (Timco and Sudom 2013).

Synonyms

Floe Ice; Sloping Structure

Definition

- Sloping Structure Offshore structure/ships with a sloping surface, which promotes the flexural failure of sea ice.
- Broken Ice Broken ice is loose ice, which consists of small floes that are broken up as a result of natural processes or active or passive intervention (ISO19906 2019).
- Floe Ice An ice field consists of ice floes of various sizes. The ice floes can be as large (in the order of kilometers) as being considered as level ice and as small (in the order of meters) as being considered as rubble ice (Lu 2014). This is a more general concept and includes

- Splitting Failure both the conventionally discussed “level ice” and “broken ice” conditions. It is a type of in-plane failure of an ice floe due the “wedge out” ice – structure contact force.
- Flexural Failure It is a type of out-of-plane failure of an ice floe featuring the radial cracking and circumferential cracking of the ice floe. The governing force is controlled by the initiation of circumferential cracks.
- Radial Cracking When an ice floe is under a vertical contact force, an out-of-plane deformation is taking place on the ice floe. Normally, radial cracks shall emanate from the loading area and propagate further away from the loading area. The radial cracks’ propagation distance is limited.
- Circumferential Crack Following the propagation of radial cracks, circumferential cracks shall develop. The initiation of circumferential crack determines the failure of an ice floe.

Scientific Fundamentals

Floe Ice

Ice floe’s size ranges from around 10 m to 10 km (Leppäranta 2011). Therefore, floe ice can be as large as “level ice” and can be as small as broken ice floes. Figure 1 shows a typical ice field in the Arctic and demonstrates the discrete features of the Arctic. The Arctic sea ice is by no means a continuous ice sheet as would often be assumed in the concept of “level ice.” Floe ice is a more general term that combines both the level ice and broken ice conditions (Lu 2014).
For sloping structure and level ice interactions, one can refer to the dedicated entry of this

encyclopedia. Here, we shall mainly present the broken ice features.

Broken Ice and Structure Interactions

Broken ice-structure interactions are not as well studied compared to those in the level ice condition. One reason is that apart from material properties, there are more parameters involved in describing a broken ice field, e.g., floe size,

geometry, ice concentration, ice thickness, and ice pressure. For level ice, apart from material properties, ice thickness is generally sufficient for ice loads calculations. Another reason is that a broken ice field typically leads to lower ice loads compared with those in a level ice condition. However, level ice is just a theoretical simplification; the actual Arctic generally consists of discontinuous features, such as ice ridges, leads, or ice floes of varying sizes, which form a broken ice field. A typical broken ice field in nature can be found in the Marginal Ice Zone (MIZ), which stretches approximately 100 km from the ice edge (Weeks 2010), where ice floes are primarily broken off by gravity waves (see Fig. 2).

Studying broken ice-structure interactions is of significant practical value. First, a great portion of a structure’s service time is within broken ice fields (e.g., see Fig. 3a). It is beneficial to gain an understanding about a structure’s most frequent loading condition.

Second, nowadays, the concept of floating Arctic offshore structures has become extremely attractive as opposed to traditional fixed Arctic offshore structures. This interest is driven by the desire to perform Arctic exploration and exploitation in deeper Arctic waters (i.e., deeper than 100 m (Hamilton 2011, Riska and Coche 2013)), and also the various flexibilities floating structures offer (e.g., disconnection in the face of extreme ice features). However, due to the limitation of

Sloping Structure: Floe Ice Interactions, Fig. 1 Mosaic of aerial photograph of summer pack by Hall in 1978 (Rothrock and Thorndike 1984)

Sloping Structure: Floe Ice Interactions, Fig. 2 Marginal Ice Zone during the KV-Svalbard Research Cruise, March 2012 in the Northern Barents Sea: (a) a sharp transition between open water and MIZ

with short waves and small ice floes (less than 1 m); (b) MIZ with long waves and large ice floes (approximately 100 m across)

Sloping Structure: Floe Ice Interactions, Fig. 3 Examples of broken ice-structure interactions (a) Oden transiting in Fram Strait in August, 2012; (b) Ice

management operation generating a broken ice field for the protected vessel, i.e., Kulluk (after (Wright 1999))

Sloping Structure: Floe Ice Interactions, Fig. 4 Global splitting and local bending failure for (a) a conical structure in the model ice tank, HSVA, and (b) Oden in the Greenland Sea (September, 2012)

mooring lines and dynamic positioning (DP) systems, a floating system is typically supported with ice management operations (Palmer and Croasdale 2013), e.g., the floating structure, Kulluk, in the Canadian Beaufort Sea (see Fig. 3b). The goal of an ice management operation is to create a relatively “open” ice condition that consists of small ice floes with low concentration. Therefore, ice loads calculations within a broken ice field become increasingly important.

However, ice loads calculations for a sloping structure within a broken ice field are still in preliminary stage and are considered only for highly idealized scenarios. One of the most simple approaches is to idealize a broken ice field as level ice according to the *equivalent ice thickness*

concept (Keinonen 1996). Then, all the previously developed methods for level ice conditions can be applied by modifying the thickness information. However, as cited by Riska and Coche (2013), a separate study has shown that this concept only gives a better result for ship transit calculations (though a higher transit speed can be predicted) than for ice loads estimations.

Failure Modes of Floe Ice

During floe ice – sloping structure interactions – two major failure modes of the ice floes have been frequently observed (see Fig. 4). These are:

- Global in-plane splitting failure (Lu et al. 2015a)

Sloping Structure: Floe Ice Interactions, Fig. 5 Simplified global contact force and an ice floe's subsequent failures

- Local out-of-plane flexural failure (Lu et al. 2015b)

These two failure modes are competing with each other (Lu et al. 2016) and are frequently observed in both model ice tank tests (see Fig. 4a) and in field observations (see Fig. 4b).

Generally speaking, when the floe ice is rather huge or with significant confinement, only the local out-of-plane failure shall take place. However, when the floe ice is relatively small and with less confinement, the global splitting failure shall take place to fracture the entire ice floe and reduce the ice resistance. The global splitting failure of an ice floe can be considered as a load-releasing mechanism (Lu et al. 2015a).

Interaction Process

As a sloping structure (e.g., an icebreaker) impacts with an ice floe, as shown in Fig. 5① to ②, complicated stress field forms within the contact area. However, from a global

perspective, three different contact force components can be isolated along with the global coordinate system (see Fig. 5③). These are a vertical force component F_z , which leads to a potential out-of-plane flexural failure, a pair of horizontal loads F_y , which lead to a potential in-plane splitting failure, and another in-plane force component F_x , which increases the compression within the ice floe.

The force components F_z and F_y are considered as the direct source for the dominant out-of-plane failure and in-plane failure separately.

If a sloping structure is interacting with a relatively large ice floe (e.g., level ice), an ice floe's lateral boundary confinement is significant, or if the contact between the structure and the ice floe leads to a fairly large vertical force component, then the ice floe's dominant failure mode is expected to be a local out-of-plane flexural-type failure, as shown in Fig. 6. On the contrary, for a relatively small ice floe, who has limited/no lateral confinement, its dominant failure mode is expected to be a splitting failure mode, as shown in Fig. 7.

Sloping Structure: Floe Ice Interactions, Fig. 6 Dominant local out-of-plane flexural failure

Sloping Structure: Floe Ice Interactions, Fig. 7 Dominant global in-plane splitting failure

The competition between these two dominant failure modes at the initial floe ice – sloping structure contact – is illustrated in Fig. 5④. It is important to formulate the needed force to arouse these different failure modes and thereby determine which is the dominant failure mode.

Calculation Methods

Different methods are available to calculate the splitting and flexural type failure modes of an ice floe. These methods can largely be categorized into those based on numerical methods, analytical methods, and empirical methods.

In this entry, we will mainly focus on the analytical methods and their derived conclusions. Related numerical methods are presented in a different entry.

Local Out-of-Plane Flexural Failure

The out-of-plane flexural type failure is mainly influenced by the size of the ice floe and ice thickness. Depending on the floe size, three different scenarios can take place (see Fig. 8):

- Direct rotation of a small ice floe
- Radial crack of an ice floe with size less than 2ℓ (the formulation of ℓ is given in Eq. (2))
- Circumferential crack formation

The direct rotation of a small ice floe can simply be a floating rigid body problem, and its formulation has been given by Lu et al. (2016). The radial crack of a small ice floe is a “plate on elastic foundation” problem. Analytical solution of this type of problem can be solved by the symplectic method (Li et al. 2013). These “failures” in Fig. 8a and b occur usually for small ice floes and

Sloping Structure: Floe Ice Interactions, Fig. 8 Different scenarios of an ice floe under an out-of-plane vertical force

contribute to relatively small ice load (i.e., F_Z). Usually it is the out-of-plane bending failure of a semi-infinite ice floe that leads to the largest vertical contact force. Such failure process involves the development of both radial cracks and circumferential cracks (see Fig. 8c) (Kerr 1976; Kerr and Kwak 1993). It is normally the initiation of circumferential crack that leads to the final failure of the ice floe. Extensive research has been conducted in

this regard (see e.g., (Bažant 2008, Kerr 1976, Kerr and Kwak 1993, Dempsey et al. 2000, Sodhi 1995, 1996, 1997; Dempsey et al. 1995, 1998; Nevel 1958, 1961, 1965)).

As a static approximation, for the vertical direction contact force F_Z , which leads to the out-of-plane bending failure, the simplified formula by Nevel (1972) can be adapted to in Eq. (1):

$$F_Z = \begin{cases} \frac{\sigma_f h^2}{3} \tan\left(\frac{\alpha}{2}\right) \left[1.05 + 2\frac{\delta}{\ell} + 0.5\left(\frac{\delta}{\ell}\right)^2 \right] & (\alpha \leq 90) \\ \frac{m\sigma_f h^2}{3} \tan\left(\frac{\alpha}{2m}\right) \left[1.05 + 2\frac{\delta}{\ell} + 0.5\left(\frac{\delta}{\ell}\right)^2 \right] & (90 < \alpha \leq 180) \end{cases} \quad (1)$$

in which,

σ_f is the flexural strength of sea ice, [kPa] α is the angle of the wedge where the local bending failure occurs, in [deg]

δ is the maximum penetration depth and is considered equivalent to the loading area size at the wedge tip, [m]

m is the number of wedges that are bent off from the original ice sheet and is set as a random number between 2 and 3 (based on lab and field observations)

ℓ is the characteristic length [m] of sea ice and is calculated by Eq. (2):

$$\ell = \left(\frac{Eh^3}{12\rho_w g} \right)^{1/4}, \quad (2)$$

in which, E , ρ_w , and g are the Young's modulus [kPa], water density [kg/m^3], and gravitational acceleration [m/s^2], respectively.

Global In-Plane Splitting Failure of an Ice Floe

The in-plane splitting type failure, however, is not as thoroughly studied as the out-of-plane type flexural failure. Among many obstacles to achieve a general analytical solution is the arbitrary geometries of an encountered ice floe. Bhat (1988) and Bhat et al. (1991) offered finite element method (FEM) results for the idealized square and disk-shaped ice floe's splitting. Later, Dempsey et al. (1993) offered the weight function-based analytical solution to characterize the splitting of a square ice floe. The analytical solution was

further extended to rectangular ice floes of arbitrary width to length ratio (Dempsey and Mu 2014). After summarizing previous research effort (Lu et al. 2015a) and developing analytical formulas for crack kinking in off-center splitting scenario (Lu et al. 2018b, c), the analytical framework to characterize the splitting failure of an ice floe can be constructed. However, the utilized analytical solutions to describe the splitting of an ice floe of arbitrary geometry are not an exact solution; it is more an approximation. To achieve more accurate results on the splitting failure of an arbitrary ice floe, a computational approach can be adopted, e.g., by the eXtended Finite Element Method (XFEM) (Lu et al. 2018a). In this entry, we shall only focus on the analytical fracture approach.

In summary, for the splitting failure modes, two types of splitting scenarios can be considered: the analytical formulas to deal with the central

splitting and off-center splitting scenarios are presented in Eqs. (3) and (4) to calculate the “splitting force term” F_Y (see Fig. 7).

$$F_Y(a) = \frac{hK_{IC}\sqrt{L}}{H(a, 0)} \quad (3)$$

in which,

K_{IC} is the fracture toughness of sea ice, [$\text{kPa}\sqrt{\text{m}}$]
 $H(a, 0)$ is the weight function of a rectangular ice floe with a centered edge crack. Its formulation can be found in Dempsey and Mu (2014)
 a is the nondimensional crack length given by $a = A/L$, whereas A is the crack length and L is the length of the an idealized rectangular ice floe

$$\begin{aligned} W_1 &= \left(\frac{F_X}{hK_{IC}} \right)^2 \left[f_1^2 \left(\frac{A_0}{W_1}, \beta_{YX} \right) + f_2^2 \left(\frac{A_0}{W_1}, \beta_{YX} \right) \right] \\ \beta_{YX} &= \frac{F_Y}{F_X} \\ f_1 \left(\frac{A_0}{W_1}, \beta_{YX} \right) &= \sqrt{\frac{4\pi}{\pi^2 - 4}} \left(\frac{A_0}{W_1} \right)^{-1/2} \left(\beta_{YX} - \frac{1}{\pi} \right) + \frac{2.0284(A_0/W_1) + 2.9890}{(A_0/W_1)^{-1.3569} + 1.0499} \beta_{YX} + \frac{1}{2} \frac{0.1856 - 0.2174(A_0/W_1)^{0.1635}}{(A_0/W_1)^{-6.2861} + 0.4092(A_0/W_1)^{0.1635}} \\ f_2 \left(\frac{A_0}{W_1}, \beta_{YX} \right) &= \frac{1.8134(A_0/W_1) + 0.5498}{(A_0/W_1)^{-1.4702} + 1.2041} \beta_{YX} + \frac{1}{2} \frac{0.4051 - 1.3238(A_0/W_1)^{0.4339}}{(A_0/W_1)^{-0.9953} + 1.0099(A_0/W_1)^{0.4339}} \end{aligned} \quad (4)$$

In Eq. (4),

A_0 is the length of the initial radial crack due to local bending failure, in [m]; it can be calculated as $A_0 = 2\ell$, with the characteristic length ℓ formulated in Eq. (2).

W_1 is the distance from the contact point to the closest free edge. The width of the bounding box of an arbitrary floe can be written as: $W = W_1 + W_2$ and $W_1 < W_2$. In general, $W_2 \geq 1.5 \cdot W_1$ for Eq. (4) is required to be valid. Otherwise, Eq. (3) is a better approximation.

$\beta_{YX} = F_Y/F_X$ represents the contact force ratio (see Fig. 5). The contact force F_X opposite to the

ship's transit direct has a tendency to close the splitting crack.

Failure Map

With the previous introduced analytical formulae, we can investigate each parameter's influence on the failure modes during floe ice – sloping structure interactions. It is the failure mode contributing to the least ice load that shall take place. Given this assumption and using typical ice properties and thickness information, two examples of failure map are shown in Fig. 9. In these two failure

Sloping Structure: Floe Ice Interactions, Fig. 9 Failure map of an ice floe while interacting with a sloping structure with $\beta_{YX} = 0.5$

maps, for illustration purpose, the contact property has been fixed as $\beta_{YX} = F_Y/F_X = 0.5$.

The general observation from the failure maps is:

- The direct rotation of an ice floe is anticipated if floe size $\leq \ell$.
- Radial or circumferential cracking of a finite size rectangular ice floe is expected if the floe length or width falls in the range of $(\ell \sim 2\ell)$.
- Ice floes with both length and width larger than 2ℓ can be considered as a semi-infinite ice floe whose failure is featured by sequentially forming radial and circumferential cracks. Nevel's (1972) approximate solutions (Eq. (1)) can be utilized to calculate the vertical force that leads to this failure type.
- The in-plane splitting failure only takes place for intermediate ice floes, and thicker ice has a high change to be split.

Applications

As floe ice is a more general ice condition in the Arctic, the theories and method presented in this

entry have wide applications regarding Arctic structural design and Arctic marine operations.

The analytical solutions introduced can be implemented in a numerical simulator to model the fracture of ice floes. This has been partly or fully achieved in simulators, e.g., (Lubbad and Løset 2011; Septseault et al. 2014; Dudal et al. 2015). These simulators have been widely used in Arctic offshore structural designs, e.g., calculation of the global ice load on the Swedish ice-breaker Oden (Raza et al. 2019; Lubbad et al. 2018), the salvage operation of the stranded fishing boat, Northguider (Berg et al. 2020; Lubbad et al. 2020), etc.

Moreover, the theoretical results have great implications to Arctic marine operations. For example, an often-raised question on the target floe size for an ice management operation can be found in the failure map. As ice failure is less likely when the floe size is less than 2ℓ , this floe size can be set as the target. Additionally, during ice management operations, the parallel channel's spacing can be optimized by using Eq. (4) presented above. The aim is to fracture more ice with minimal operation effort (i.e., more spacing distance between parallel channels).

Level ice; Sloping structure

Definition

Sloping structure: Offshore structure/ships with a sloping surface which promotes the flexural failure of sea ice.

Level ice: Level ice is a region of ice with relatively uniform thickness (ISO19906 2019).

Ice breaking load: The force required to break the incoming level ice. It takes place in the initial ice breaking phase. Normally the beam on Winkler-

type foundation formulation can be utilized to calculate this force term. However, for wide sloping structures, the influence from rubble accumulation should be accounted for (Lu et al. 2014a).

Ice breaking length: During level ice and sloping structure interactions, ice fails mainly in flexural failure mode and presents certain length characteristics. The general trend is that higher interaction velocity leads to shorter ice breaking length. More secondary ice breakings (e.g., aroused by rubble accumulation) also leads to shorter ice breaking length.

Ice rotating load: The force required to rotate the already broken ice. This happens during the ice rotating phase. Depending on the rubble accumulation amount, ice block length, and ventilation effect, secondary ice breaking process can also take place.

Ventilation effect: During ice rotating phase, depending on the ice rotating speed, it possible that the water does not have fill the top of the rotating ice block, leaving a ventilated area above. This introduces a significant amount of extra force during the ice rotating phase (Valanto 2001; Lu et al. 2012a).

Backfill effect: During ice–sloping structure interactions, due to the inherent slow interaction speed, the ventilated area can be partially flooded by the backfill water. This can alleviate certain amount of ice rotating load. This load term is highly dependent on the rotating speed. Usually a fully ventilated scenario is assumed for level ice–ship interactions (Valanto 2001) and a partially ventilated process can be assumed for level ice–wide sloping structure interactions (Lu et al. 2013, 2014a).

Scientific Fundamentals

Sloping Structure Types

The sloping surface of an sloping structure can be conical, multifaceted, or flat (ISO19906 2019); and the structure can have either downward or upward sloping surfaces.

The conical sloping structure has been widely utilized in the confederation bridge piers (Mayne 2007), jacket offshore structures (Yue et al. 2007),

wind turbine foundations (Barker et al. 2005), light houses (Määttä et al. 1996; Brown and Määttä 2009), etc.

In addition, it is possible to separate sloping structures into those that are wide and narrow sloping structures (Lu et al. 2014a).

Interaction Process

Level Ice–Ship Interactions

Regarding level ice–ship interactions, previous researchers, e.g., (Kotras et al. 1983; Naegle

1980; Lindqvist 1989; Kämäräinen 2007), have identified at least three major interaction phases and several ice load components that can be studied separately. For example, the level ice–ship interaction processes were depicted by Kotras et al. (1983) as:

- Icebreaking phase (shown in Fig. 1a, b, and c), in which crushing failure of ice occurs at the initial contact followed by bending (or flexural) failure of the intact ice sheet into wedge-shaped broken ice blocks.

Sloping Structure–Level Ice Interactions, Fig. 1 Level ice and ship interaction processes. (After Kotras et al. 1983)

Sloping Structure–Level Ice Interactions, Fig. 2 Comparative contributions of different load components versus interaction speed. (After Valanto 2001)

- Ice rotating phase, in Fig. 1c and d denote the ice rotating process involving the “ventilation” effect (i.e., no water flooding on top of the rotating ice piece, which creates huge pressure differences above and below the rotating ice blocks).
- Ice rubble sliding phase: as a new interaction circle begins, the last plot in Fig. 1e implicitly illustrates that ice rubbles sliding along the ship hull signifies the rubble transportation process.

Along with this depiction, Valanto (2001) quantified the comparative contribution of different force components, as shown in Fig. 2.

Considering the ice drifting velocity, the shaded area in Fig. 2 is approximately the interested region for level ice and fixed or floating offshore structure interactions. Within the shaded area, several of the force components identified by Valanto (2001) are expected to be absent or insignificant (e.g., ice floe slamming at the end of an ice rotating phase). In general, we highlight the potential largest three force components, i.e., the ice loads due to the ice-breaking phase (i.e.,

labeled as “dynamic bending and acceleration” in Fig. 2), the ice loads due to the ice rotating phase (i.e., labeled as “ice floe rotation” in Fig. 2), and the rubble transportation phase (i.e., labeled as “ice sliding phase” in Fig. 2). Figure 2 shows that the ice sliding phase contributes almost half the total ice resistance an ice-going ship encountered.

The Lindqvist formula (1989) can be utilized to calculate these different force terms.

Level Ice–Narrow Sloping Offshore Structure Interactions

In terms of level ice interacting with a sloping offshore structure, ISO19906 (2019) illustrates the process in Fig. 3 with an example of an upward sloping conical structure. A vast literature source exists that proposes various calculation methods for all of these force components (detailed literature review can be further explored in literature, e.g., (Lu et al. 2014a)).

As an analogy to the level ice–ship interaction research introduced in the previous section, the plots can also be categorized into:

Sloping Structure–Level Ice Interactions, Fig. 3 The interaction process between level ice and an upward sloping structure

- Ice breaking phase shown in Fig. 3a
- Ice rotating phase shown in Fig. 3b
- Ice rubble transportation phase shown in Fig. 3c, d, and e

Unique physical process occurs within these three different phases. From a mechanical point of view, for the ice breaking phase, the major physical process is fracturing of the incoming level ice. Ice material can be treated as purely elastic; for the ice rotating phase, depending on the interaction speed, rather fierce fluid–structure interaction scenarios occur (an ice piece can either be treated as an elastic body or a rigid body depending its actual size (Lu et al. 2013); for the rubble transportation process, it is primarily a multibody interaction system, and each single ice rubble can be treated as a rigid body; or the entire rubble volume could even be idealized as a

continuum (e.g., Serré and Liferoev 2010; Serré 2011).

The formulas proposed by Croasdale and Cammaert (1994) and adopted in the standard (ISO19906 2019) can be utilized to calculate these different force components.

Level Ice–Wide Sloping Offshore Structure Interactions

The same three interaction phases as presented before they can be identified for the interaction between level ice and a wide sloping structure. The only difference with regard to wide sloping structure interaction is the influence of rubble accumulation. This is illustrated in Fig. 4.

The presence of ice rubbles influences both the icebreaking and ice rotating phases. Relatively new formulations, comparing to those utilized by Croasdale and Cammaert (1994), can be found in

Sloping Structure–Level Ice Interactions, Fig. 4 The proposed interaction mechanism between level ice and a wide sloping structure under the influence of rubble accumulation

the literature (Lu et al. 2014a). Alternatively, one can also resort to numerical simulation approach, e.g., Discrete Element Method (DEM) (Paavilainen and Tuhkuri 2012, 2013; Paavilainen et al. 2006, 2009, 2010, 2011), to simulate the rubbing process and calculate the ice load on a sloping structure.

The design ice load in this case is found to be the buckling of force chains (Paavilainen and Tuhkuri 2013).

Calculation Methods

As the previous section illustrates, the interaction between level ice and a sloping structure involves distinct physical processes such as ice fracture, fluid structure interaction, and ice rubble accumulations. Different calculation methods are available for different interaction processes, and it is also possible to calculate all three processes in one

set of formulations/numerical simulations. Different categories can be identified as follows:

- A purely analytical approach: e.g., analytical solutions for level ice and sloping structure interactions (Croasdale and Cammaert 1994; Ralston 1977, 1980; Lindqvist 1989; Lu et al. 2013, 2014a). These analytical solutions typically involve a large number of assumptions, though are effectively suitable for generating a sizeable result pool for probabilistic analysis for the design stage.
- A purely numerical approach: earnest ice material modeling based on the finite element method (FEM) that accounts for the fracturing of ice floes and the discrete element method (DEM), which accounts for the rubble transportation process. With regard to the ice fracture simulation, the cohesive zone model utilized in FEM (e.g., Lu et al. 2012b, 2014b; Konuk et al. 2009a, b; Konuk and Yu 2010,

Kuutti et al. 2013, Wang et al. 2018, 2019) and DEM (Tuhkuri and Polojärvi 2018) are of great potential. More methods of this category shall be elaborated in the entry ► “Numerical Simulation Floe Ice–Sloping Structure Interactions”.

- A hybrid “empirical + numerical” approach with both empirical and numerical implementations, e.g., the numerical simulators developed by Liu et al. (2006) and Su et al. (2010) used empirical formulae to calculate the ice breaking and rubble transportation phases, where a numerical approach was adopted to detect contact between the ship hull with an intact ice sheet.
- A hybrid “analytical + numerical” approach to simulate general ice–structure interactions (including ice–sloping structure interactions). Analytical formulas to simulate the typical ice failure modes (Lu et al. 2015a, b, 2016, 2018a, b) are available, and can be coupled with existing multibody dynamic simulators to perform ice–sloping structure interaction simulations, for example (Lubbad and Løset 2015; Lubbad et al. 2015, 2018a, b; Tsarau et al. 2018).

Applications

The theories and methods presented here have wide applications in most man-made structures’ design in icy waters. For example, ice-going vessel’s global ice load calculations with the purely analytical methods (Suyuthi et al. 2011; Kjerstad et al. 2018; Kim et al. 2020); designs of ice-breakers with the empirical + numerical method (see the reference above); and calculations of ice load on a drilling island in the Caspian Sea (Croasdale 2012), on light houses (Määttänen and Hoikkanen 1990; Määttänen et al. 1996), on bridge piers (Brown and Määttänen 2009; Mayne 2007), and on various offshore platforms in the high North.

Soft YOKE Single Point Mooring System

Yougang Tang
Tianjin University, Tianjin, China

Synonyms

Mooring system; Positioning system; Single point mooring system

Definition

The soft YOKE single point mooring system is a kind of marine single point mooring device (Deng 2012). The ship such as the oil tanker is positioned in the predetermined sea area through a freely

rotatable fixed point, and meanwhile, has the functions of transporting well flow, electricity, and communication. The soft YOKE single point mooring system can make the hull such as Floating Production Storage and Offloading System (FPSO) have the wind direction effect, allowing the moored hull to rotate 360° around the mooring point, so that the hull always along the resultant force direction of wind, waves, and flow (Xiao 2016). It is in the state of minimum stress, and it also reduces the motion response of the hull and the mooring load on the hull. The soft YOKE single point mooring system is one of the important devices in the offshore oil development. It has two main functions: one is to locate the hull such as FPSO; the other is used as the terminal for delivering crude oil. The soft YOKE single point mooring system can moor the super large FPSO or oil tanker, which is strong against the marine environment. However, due to the rigid connection to the seabed, the system is mainly suitable for shallow water operations (Wei 2012).

Development History

In 1974, a single point mooring device for steel structure connecting oil tankers was developed in the world (Shouwei et al. 2006). The A-shaped steel frame was used instead of the steel wire rope to connect the oil tanker, which avoided the collision between the oil storage tank and the floating tank, and reduced a lot of maintenance work. It is called rigid arm single point mooring system. In 1980, the first floating production, storage, and loading and unloading system of rigid arm single point mooring was installed in the Philippine waters. The device can be used for oil and gas processing, storage, and external transportation. The rigid arm single point mooring device is shown in Fig. 1.

The rigid arm mooring method is mainly composed of a triangular steel structure and a tower (Geng-xian 2009). The triangular steel structure is connected to the tanker at one end and to the tower at the other end. This mooring method allows the tanker to rotate to the direction that is least affected by environmental forces, but the surge

Soft YOKE Single Point Mooring System, Fig. 1 Rigid arm single point mooring system

Soft YOKE Single Point Mooring System, Fig. 2 Soft YOKE single mooring system. (a) Above water soft YOKE single mooring (b) Under water soft YOKE single mooring

and pitch motion of the tanker is constrained. The load of the tanker's surging process is transmitted to the rigid arm and the tower, which is easy to cause damage to the triangular steel frame.

In November 1981, soft YOKE single mooring system was developed and it was designed and installed at offshore oil field in Philippines. According to the position of YOKE, above or below the water surface, soft YOKE single mooring system can be divided into above water soft YOKE single mooring system and underwater soft YOKE single mooring system. At soft YOKE single mooring system was well developed, as shown in Fig. 2.

Operational Principle and Component

The tower soft YOKE single mooring system mainly includes mooring arms, ballast tank, YOKE, jumpers, hose deck, turntable deck,

swivels, manifold deck, main deck structure, and tower. A mooring support structure at the bow of the vessel is installed for connecting the mooring device as shown in Fig. 2. The upper end of the mooring arm is hinged to the mooring support structure on the tanker, the lower end of the mooring arm is hinged to the ballast tank, and the YOKE is hinged to the turntable deck. The jumpers deliver crude oil from the pipeline to the tanker. This form of single point mooring facilities allows six degrees of freedom motion of tanker. The quality of ballast tanks is hundreds of tons, and it can provide the recover stiffness during the surge and pitch motion of the tanker, as shown in Fig. 3 (Shouwei et al. 2006; Geng-xian 2009; Yao 2013).

The upper and the lower part of the mooring arm are connected with the FPSO bow mooring bracket and the soft YOKE, respectively, through three axis hinges. When the mooring system is in

Soft YOKE Single Point Mooring System, Fig. 3 The composition of single point mooring facilities

equilibrium, the mooring leg of the suspended YOKE is vertical. YOKE is driven by mooring legs when FPSO surges, and YOKE generates restoring force under the action of ballast gravity, which makes FPSO return to the equilibrium position of surge motion. In addition to the weather vane effect, such single point mooring device does not restrict the roll and yaw motion of the tank. Surge and pitch motion can also occur. When the wind vane effect moves the tanker to the minimum force position, the surge motion is decayed because of the inertia of the hundreds of tons ballast tank. It reduces the force acting on YOKE and horizontal force on tower, thus the tower can be prevented from being damaged by a large horizontal load. It is the advantage of soft YOKE single mooring system.

The mooring structure of the on-water soft YOKE mooring system is above the water surface. All structures, especially the mooring arms and rotating parts, are above the water surface for monitoring and maintenance. It has a defect that horizontal thrust acts on the top of the tower structure, causing a large horizontal overturning moment. It is easy to cause the tower structure to

fall; the underwater soft YOKE mooring system is below the water surface, and the force of YOKE acts on the bottom of the tower, and the overturning moment acting on the tower is small, which is beneficial to the tower to maintain stability. The shortcoming is that the mooring arm and the rotating component are below the water surface, especially the mooring arm is subjected to a large environmental force, which easily causes damage, and the underwater structure and components are not convenient for monitoring and maintenance. At present, the offshore oil and gas development field tends to use the on-water soft YOKE mooring system.

The functions of the various parts of the single-point soft YOKE mooring system are as follows:

1. Tower-Jacket Structure

The single-point mooring system has a slip ring channel on which the liquid medium is continuously transported, so that corresponding oil risers, water pipes, and cable guards are also disposed under the tower. To prevent damage to these components, these pipes are placed inside the tower.

In addition, since the single-point tower is the center of rotation of the FPSO weathervane movement, it is subject to greater mooring forces.

2. Manifold Deck

The lowermost deck above the tower-jacket is a manifold deck, which is mainly equipped with oil and water pipelines, receiving ball pigs, cable junction boxes, and other facilities. Its center is penetrated by the general column, and the oil and water pipes are merged and then enter the upper slip ring system (fluid rotating passage) from the general column.

3. Turntable Deck

Above the manifold deck is a turntable deck, which is located in the middle of the tower-jacket and is the most special point of a single point. As a boundary between the single point mooring fixed part and the rotating part, the lower manifold deck and the tower are fixed structures, and the oil water passage, the electric instrument slip ring and the hose deck above it are all rotating parts. At the center of the turntable deck is the main bearing that rotates in a single point system, which supports the slip ring system, leak recovery system, and automatic lubrication system.

4. Hose Deck

Hose deck is in the top of the mooring tower, on one side of which near the FPSO the arc plate is set to make the arrangement of the jumper hose and cable convenient, on the other side the lifting crane is set to daily operation. In addition, hose deck is also equipped with hoses deck winch is used to drag the hose and cable.

5. Mooring Connected Components

FPSO is connected to the single point mooring tower by ship stem mooring support, mooring legs, soft YOKE, and turntable, which is shown in Figs. 4 and 5.

6. Slip Ring System

Slip ring system is a key component of the single point mooring tower, which is composed of communication slip ring, electro-slip ring, liquid slip ring (also called fluid rotary joint), and so on from top to bottom. The liquid slip ring is the core of oil-water transportation,

Soft YOKE Single Point Mooring System, Fig. 4 Ship stem mooring support

Soft YOKE Single Point Mooring System, Fig. 5 Mooring legs and YOKE

connecting the fluid pipeline equipment between the rotating part and the stationary part, as shown in Fig. 6. A plurality of fluid rotating joints is usually arranged to be stacked together. Each rotating joint consists of an inner ring (stator) and an outer ring (rotor), of which the inner ring is fixed on a single point of the general column and connected with the riser, the outer ring is connected to the mooring device and rotated with the FPSO.

Soft YOKE Single Point Mooring System, Fig. 6 The inner ring and outer ring of liquid slip ring

Soft YOKE Single Point Mooring System, Fig. 7 HYSY117. (Source CNOOC)

Application

With the development of the Soft-YOKE Single-point Mooring System, the YOKE-type SPM is less used for the offshore engineering structures. Due to the mooring arms and YOKE structure, a large horizontal thrust occurs. When the water depth is increasing, the height of the tower, as well as the horizontal thrust of the YOKE, is also enlarged. In case of the system collapsing, the main dimensions of the tower structure should be amplified, which leads to the explosive cost incensement. Therefore, the Soft-YOKE SPM is suitable for the shallow water-depth area.

At present, the worldwide largest FPSO moored by Soft-YOKE SPM is HYSY117 (Geng-xian 2009), which is working on the Penglai 19-3 offshore oilfield in Bohai Sea, China. Its overall length is 323 m, and width is 63 m. The oil storage capacity is two million BBLs, and the daily processing capacity of the crude could reach 190,000 BBLs, which means the HYSY117 could handle ten million cubic meters crude annually. According to the Soft-YOKE SPM, the FPSO could be long-term moored in its working area without extrication for its designed lifetime, say 25 years for HYSY117 (Yao 2013). Moreover, the whole system could bear 100-year sea state (Fig. 7).

Definition of Sonar

The word “SONAR” is the English abbreviation of Sound Navigation And Ranging. It is an electronic equipment that uses the propagation characteristics of sound waves underwater to complete tasks such as underwater detection, positioning, and communication through electro-acoustic conversion and information processing. Since the propagation of electromagnetic waves in water is much larger than that of sound waves, and no more efficient information transmission channels than sound waves have been found, sound waves are still the most ideal carrier for information acquisition in the ocean. As a result, the detection technology of underwater targets, sonar technology, was born (Elfes 1987).

Historical Moment

In 1906, Lewis Nixon, a British naval soldier, invented the first sonar, a passive listening device that was applied in the battlefield to detect submarines hidden in the water during World War I. These sonars can only be passively listened, so they belong to passive sonar. In 1915, French physicist Paul Langevin in cooperation with Russian electrical engineer Constantin Chilowski invented the first active sonar and detected the submarine by listening to the echoes reflected by the submarine. Their groundbreaking

work has had a profound impact on the subsequent sonar design (Naik et al. 2017).

Composition of Sonar

The sonar system mainly consists of two components: the dry end and the wet end. The wet end is mainly composed of hydroacoustic transducers or a transducer array, and the dry end is mainly composed of a signal source, a transmitting device, a signal processing platform, a power supply device, and a display control unit. The array is composed of a number of hydroacoustic transducers arranged in a certain geometric pattern, and its shape is usually a spherical shape, a cylindrical shape, a flat plate shape, or a line array. It consists of the receiving array, the transmitting array, or the array that can both receive and transmit. The wet end system also includes connecting cables, underwater junction boxes, preamplifiers, lifting, swinging, pitching, retracting, towing, hoisting, placing device matched with the transmission control of the sonar array, and other auxiliary equipment such as sonar shroud. The dry end system generally has a subsystem for transmitting, receiving, displaying, and controlling, wherein the signal processing platform is an information data processing operation center. The composition of the UK 2087 sonar system is shown in Fig. 1.

The transducer is the basis of the sonar equipment. It is a device that converts sound energy and other forms of energy such as mechanical energy, electrical energy, and magnetic energy. Its working principle is to use some special materials that can expand and contract under the action of electric or magnetic fields. This effect is usually called piezoelectric effect or magnetostrictive effect. This effect causes vibrations on the surface in contact with water to radiate sound waves into the water and vice versa. The transducer has two main purposes: one is to emit sound waves underwater, called a “transmitting transducer,” which is equivalent to a speaker in the air; the other is to receive sound waves underwater, called a “receiving transducer.” It is equivalent to a microphone in the air. Transducers can often be used to transmit and receive sound waves at the same time in actual use; and transducers specifically used for receiving are also called “hydrophones” (Liu and Gong 2008). Figure 2 shows the commonly used underwater acoustic transducer for sonar.

Classification of Sonar

There are many kinds of sonar which can be classified according to the working mode, equipment object, installation platform, practical use, and technical characteristics. For example, it can

Sonar Technology, Fig. 1 The UK 2087 sonar system (<https://www.savetheroyalnavy.org/listening-to-the-ocean-the-secretive-enablers-in-the-underwater-battle/>)

be divided into active sonar and passive sonar according to the working mode; it can be divided into shipboard sonar, submarine sonar, airborne sonar, and shore-based sonar according to the equipment object; according to the installation platform, it can be divided into bow sonar, flank sonar, towed sonar, buoy sonar, etc.; according to the actual use, it can be divided into detection sonar, imaging sonar, positioning sonar, communication sonar, etc.; and according to technical characteristics, it can be divided into parametric array sonar, synthetic aperture sonar, multi-beam sonar, continuous wave sonar (Wang 2009). Figures 3, 4, and 5 show several typical sonars.

Active Sonar

Active sonar emits some form of sound wave signal into the water. When a sound wave

encounters a target such as a submarine or a fish group in the water and because of the acoustic characteristics of the target are greatly different from the seawater, a large reflection is generated. The reflected echo contains many information of the target, so the presence of the target can be judged according to the received echo signal, and the distance, azimuth, speed, and other parameters of the target are measured or estimated, as shown in Fig. 6. Specifically, the distance between two targets can be inferred by the time interval of echo signal and the transmitted signal, and the direction of the target can be inferred from the normal direction of the echo wave front, and radial velocity of the target can be inferred from the frequency shift between the echo signal and the transmitted signal. In addition, the shape, size, nature, and motion state of the target can be identified by the amplitude, phase, and variation of the echo. Most of the active sonars use a pulse system. In recent years, continuous wave systems have also been adopted, which are suitable for detecting icebergs, reefs, shipwrecks, seabed, fish schools, frogmen, mines, and submarines.

Passive Sonar

The sonar that uses the receiver transducer array to receive the noise or signal emitted by the target itself to detect the target is called passive sonar. Since the passive sonar itself does not emit a signal, the target will not be aware of the presence of sonar. The biggest difference between

Sonar Technology, Fig. 2 Underwater acoustic transducer

Sonar Technology, Fig. 3 Bow sonar (<https://www.navsea.navy.mil/Home/Warfare-Centers/NUWC-Newport/What-We-Do/Detachments/Seneca-Lake/Facility-Power/>)

Sonar Technology,

Fig. 4 Dipping sonar
(<https://www2.l3t.com/oceansystems/contact.htm>)

**Sonar Technology,**

Fig. 5 Towed AN/SQQ-89A(V)15 sensor suite
(<https://www.militaryaerospace.com/computers/article/16715038/navy-asks-lockheed-martin-to-build-towedarray-sonar-systems-for-navy-surface-warships>)

passive sonar and active sonar is that the former cannot obtain the waveform of the noise or signal emitted by the target in advance and usually the target noise is used as a signal, which becomes very weak after long-distance propagation. As a result, passive sonar often works in low signal-to-noise ratio conditions and thus requires more signal processing measures than active sonar. Passive sonar has no launching parts and generally works continuously, suitable

for detecting surface ships, submarines, torpedoes, etc.

Application Field of Sonar

The application of sonar technology is generally divided into military and civilian use, and the military dominates. It is the main technical means used by underwater navies for underwater

Sonar Technology, Fig. 6 Active sonars (<https://www.g.com/mil/20715297/>)

surveillance. It is used to detect, locate, classify, and track underwater targets for water. It is also used for the navigation and communication to ensure the navigation safety and information interaction between ships and submarines or all kinds of underwater unmanned platforms. Sonar technology has also been widely used in civilian use, and sonar equipment for various purposes has been born, mainly used for marine environmental parameter acquisition, marine resource exploration, underwater navigation and positioning, underwater information transmission, etc. With the development of sonar technology, civilian sonar equipment will play an increasingly important and irreplaceable role in marine development.

Military

Anti-submarine Detection

Submarines rely on their excellent concealment and powerful weapon delivery capabilities, and the threat is increasing day by day. Therefore, anti-submarine warfare is the top priority of underwater warfare. For this reason, people have developed various anti-submarine sonar equipment based on various platforms and even anti-submarine internet. At present, the anti-submarine detection sonar mainly includes the stern sonar, the side sonar, the tow sonar, on

the ship and the submarine, the hoisting sonar, the throwing buoy sonar on the plane, the shore-based sonar on the shore, the sonar submarine standard on the specific sea area, etc. Although people laid a large net for the submarine, the actual situation is that anti-submarine is still very difficult.

Small Target Detection

There are many kinds of small underwater targets, including carrying platforms, such as various underwater unmanned vehicles, and weapons platforms, such as torpedoes, mines, and frogmen. The detection of small targets usually requires a higher operating frequency to improve the spatial and temporal resolution of the sonar, to achieve the effect of the target imaging, thereby identifying the target and assessing the threat level of the target. Small target detection sonars are usually classified according to the object of detection, such as torpedo alarm sonar, hunting thunder sonar, and anti-frogman sonar. In recent years, the development of surface underwater unmanned platforms has brought new opportunities and challenges to small target detection.

Underwater Sound Guidance

Underwater weapons are typically torpedoes and mines. In order to improve the effectiveness of these weapons, various types of sensors are generally required to give them intelligent sensing

capabilities. For example, torpedoes have evolved from early direct torpedoes to today's acoustic self-guided torpedoes. The self-guided sonar including the torpedo head and the wake self-guided sonar on the back of the torpedo, such as the sound fuze of the mine, are guided by acoustic means to improve the hit rate.

Underwater Acoustic Communication

Replacing electromagnetic waves with sounds wireless communication underwater is currently the most effective technical approach. Submarine sailing underwater requires information exchange through underwater acoustic communication; cluster control of underwater unmanned aerial vehicles also requires underwater acoustic communication support; underwater anti-submarine network construction is even more inseparable from underwater acoustic communication. In recent years, underwater preset weapons have also appeared, and wake-up and control are also required through underwater acoustic communication. At present, underwater acoustic communication has become a bottleneck restricting many underwater military applications.

Civilian Use

Ocean Mapping

Marine resource exploration, coastal engineering construction, and submarine engineering construction are all inseparable from the support of seabed topography and geology. The acoustic detection of seabed topography and geology is the fastest and most convenient technical means, which has been rapidly developed one of the important research areas of marine surveying and mapping. Equipment for marine mapping using sonar technology includes single-beam echo sounder, side-scan sonar, multi-beam sonar, synthetic aperture sonar, shallow profiler, etc., which can measure the seabed in different accuracy through various platforms.

Speed Measurement

Using the relationship of velocity to Doppler, the velocity can be estimated by measuring the

Doppler shift of the echo. The Doppler current profiler uses two sound beams at a certain angle to illuminate the water body. The suspended particles moving in the water body cause the Doppler effect of the water echo, which can be measured by measuring the Doppler shift between the two beams. It is estimated that the suspended particles are also the velocity of the water flow. When the sound beam is irradiated to the sea floor, the speed of the carrier relative to the seabed can be obtained by measuring the Doppler shift in the seafloor echo.

Underwater Positioning

When underwater submersibles work underwater, they generally need to know their relative positions in real time to achieve precise control. Acoustic methods are often used for underwater positioning, and the basic principle is triangular positioning. According to the needs of measuring distance and positioning accuracy, it is usually divided into long baseline positioning, short baseline positioning, and ultrashort baseline positioning, and the positioning accuracy can reach up to two thousandths. Ultrashort baseline positioning systems are typically installed on underwater unmanned platforms.

Marine Fisheries

Ocean fishing is a large mechanized fishing activity, so it is usually necessary to detect the fish population first and perform reasonable network operations based on the detection results. The fish finder is a sonar system that can be used to discover the movement, the location, and the range of the fish, which can greatly improve the production and efficiency of fishing. In addition, acoustic barriers can be used in marine farms to prevent shark intrusion and to prevent the escape of lobster fish.

Underwater Networking

With the increasing research activities of underwater production and the wide application of underwater unmanned platforms, the formation of underwater wireless networks in local areas will help to improve work efficiency and further realize intelligent management. For example,

a water-based router and a mobile node or a fixed node with a hydroacoustic communication module underwater can form an underwater Wi-Fi network, which can be applied to seabed observation network, offshore oil and gas platform data collection, underwater submersible cooperative networking operation, etc.

Influencing Factors

There are many factors affecting the performance of sonar work. In addition to the technical conditions of the sonar itself, the influence of external conditions is very serious. Some factors are more direct, such as propagation attenuation, multipath effect, reverberation interference, ocean noise, self-noise, target reflection characteristics, or radiated noise intensity, which are mostly related to marine environmental factors. For example, sound waves are affected by the uneven distribution of seawater medium and the influence of sea surface and sea floor during the propagation, which will cause refraction, scattering, reflection, and interference, which will cause sound line bending, signal fluctuations, and distortion, resulting in changes in the propagation path and appearance of sound shadow area, which seriously affects the range and measurement accuracy of the sonar. Factors affecting the performance of sonar work in addition to the technical conditions of the sonar itself, the influence of external conditions, are very serious. The more direct factors are propagation attenuation, multipath effect, reverberation interference, ocean noise, self-noise, target reflection characteristics, or radiated noise intensity, which are mostly related to marine environmental factors.

For example, sound waves are affected by the uneven distribution of seawater medium and the influence of sea surface and sea floor during the propagation, which will cause refraction, scattering, reflection, and interference, which will cause sound line bending, signal fluctuations, and distortion, resulting in changes in the propagation path and appearance. The sound shadow area seriously affects the range and measurement accuracy of the sonar. Modern sonar can choose the working depth and pitch angle of the array according to the sound velocity profile of the sea area and use the different propagation paths of sound waves (direct sound, sea bottom reflection, convergence area, deep sea channel) to overcome the adverse effects of underwater sound propagation conditions to improve the sonar detection distance.

Biological Sonar

Interestingly, sonar is not a patent of human beings, and many animals have their own “sonar.” The bat uses the throat to emit 10–20 ultrasonic pulses per second and receives its echoes with the ear, as shown in Fig. 7. With this “active sonar,” it can detect very small insects and 0.1mm thick metallic line. Insects such as moths also have “passive sonar,” which can clearly hear bat ultrasound outside the 40m, and thus often escape the attack. However, some bats can use high-frequency ultrasound or low-frequency ultrasound beyond the insect detection range, so that the catch rate of catching insects is still high. It seems that animals also carry out “sonar warfare” like humans.

Sonar Technology,
Fig. 7 Bat sonar (<https://askabiologist.asu.edu/echolocation>)

Sonar Technology,
Fig. 8 Dolphin sonar
 (Sarfati 2019)

Marine mammals such as dolphins and whales have “underwater sonar,” as shown in Fig. 8, which use different sound signals for predation, play, social, and alarm, and other marine mammals such as seals and sea lions can also emit the sonar signal. Numerous studies have shown that the sensitivity of dolphin’s sonar is very high. They can identify a wire with a diameter of 0.2 mm and a nylon rope with a diameter of 1 mm, can find fish school in a few hundred meters away, and can move flexibly and quickly without touching the bamboo poles in the case of blindfolded eyes through the pool filled with bamboo rafts. The dolphin sonar’s “target recognition” ability is very strong; they not only can identify different fish, can distinguish different materials such as brass, aluminum, bakelite, plastic, etc. but also can distinguish the echoes of their own voices and the sound waves replayed by people recording their voices; moreover, dolphin sonar also has emotional expression ability, and it has been confirmed that dolphins are animals with “language” and their “conversation” is through its sonar system.

In addition, animals that have lived in the depths of the ocean for many years have severely degraded their vision and have to develop super-sensitive auditory systems for hunting prey and anti-avoidance attacks. Their sonar performance is beyond the reach of modern human technology. Solving the mystery of this animal sonar has always been an important research topic in modern sonar technology.

Terrible Problems Sonar Brings

A report by the National Natural Resources Defense Council (NRDC) shows that increasing ocean noise, such as military sonar, is affecting the lives of dolphins and whales because they must rely on sound for mating, foraging, and escaping natural enemies. According to the report, the low level of ocean noise affects the long-term behavior of marine organisms, which in turn leads to their hearing loss and even death. RDC’s research suggests that the current scientific community has no controversy about military sonar that can harm, kill, and extensively destroy marine mammals. The US Environment and the Cetacean Protection Organization have also worked for many years to protect marine mammals from the effects of US sonar. The results show that sonar is closely related to the mortality of cetaceans. In addition, sonar also reduced the success rate of halibut and other fish predation but also affected the fish reproduction rate and the behavior of giant turtles. The inner ear of some fish has also been seriously injured, which directly threatens their survival (Erbe et al. 2018).

Development Trend

Due to different uses, the development trend of military sonar and sonar for civil use are not the same. Military sonar pursues a longer range of action, so it presents a development trend of low frequency, high power, and high sensitivity, while

sonar for civil use pursues more precise measurement results. Therefore, the development trend will be high frequency and broadband. With the development of materials, electronics, information, and other technologies, the advancement of sonar technology will be further promoted in underwater array, signal processing, hardware implementation, and overall design method. The new generation of sonar will have higher sensitivity and farther detection distance and higher resolution.

Synonyms

[MinDoc \(Minimum Deepwater Operating Concept\)](#); [SCF \(Single Column Floater\)](#); [SCR \(Steel Catenary Riser\)](#); [TCell \(Truss Cell Spar\)](#); [TTR \(Top Tensioned Riser\)](#)

Definition

A spar is a type of floating oil platform typically used in very deep waters and is named for logs used as buoys in shipping that are moored in place vertically. Spar production platforms have been developed as an alternative to conventional platforms. The deep draft design of spars makes them less affected by wind, wave, and currents and allows for both dry tree and subsea production. Spars are most prevalent in the US Gulf of Mexico; however, there are also spars located offshore Malaysia and Norway. ([https://en.wikipedia.org/wiki/Spar_\(platform\)](https://en.wikipedia.org/wiki/Spar_(platform))).

Spar Platform Types

Spar platforms currently in service and under construction in the world can be divided into three types, which are Classic Spar, Truss Spar, and Cell Spar.

Classic Spar – First Generation

The main body of the Classic Spar is a cylinder suspended vertically in the water. The overall diameter is large. The length is generally between 20 m and 40 m. The main draught is above 100 m, and the center of gravity is located deep below the waterline. Its bulky interior is divided into a multi-story and multicabin structure using vertical water-blocking bulkheads and horizontal decks. It consists mainly of three parts: hard tank,

SPAR Platform, Fig. 1 Classic Spar

SPAR Platform, Fig. 2 Truss Spar

midsection, and soft tank. The hard tank is located at the top of the main body and is the main source of buoyancy for the entire Spar platform. The middle section is the part from the bottom of the variable ballast tank to the top deck of the temporary float. Its main function is to rigidly connect the hard and soft cabins of the main body of the Spar platform. The soft cabin is located below the middle section and mainly provides ballast (Fig. 1).

Truss Spar – Second Generation

The design concept is to replace the middle structure of the Classic Spar cylinder with a truss structure. It uses an open space frame structure to connect the top hard and bottom soft compartments, which can save about 50% of the steel; and the central open truss structure makes the area of the Truss Spar main body greatly reduced, which lowers the horizontal external load of the platform, thereby reduces the horizontal response of the platform and the drag load caused by the

circulation. The truss structure also provides lateral support for TTR and SCR. There are normally three heave plates installed evenly in the truss, and the application of the heave plate can significantly reduce the vertical motion amplitude of the platform. Compared with Classic Spar, Truss Spar has better response performance and greatly reduces the amount of steel used. Therefore, it has been widely used and becomes the most popular type of Spar platform (Fig. 2).

Because Truss Spar is the most popularly used type, its performance characteristics are introduced. Compared to other types of Spar platforms, the Truss Spar platform offers superior response performance and lower cost. This is mainly determined by its structural characteristics and reflects its superiority.

1. Due to the adoption of the open frame structure, it leads to the weight reduction. Meanwhile, the main surface area of the platform is greatly reduced, and the horizontal external

force load of the platform is reduced, thereby reducing the motion response of the platform in the horizontal plane.

2. The heave plate structure on the open body of Truss Spar platform greatly improves the stability of the platform. It not only can provide a certain ballast weight but also greatly lowers the heave motion amplitude, because the heave plates interact with the upper and lower seawater and produce a large viscous damping and added mass of heave motion. The natural frequency of the heave motion is further reduced, evading the likelihood of resonance in the wave frequency.
3. Due to the truss structure of the platform, the weight and external load are reduced, and a smaller-dimensional mooring system can be used.
4. Flexible subsea pipelines and steel catenary risers can be attached to the hard and soft tanks of Spar platform.

Cell Spar – Third Generation

There is only one Cell Spar in the world. Its hull is composed of several cylinders. The upper part of cylinders of the Cell Spar provides the overall required buoyancy. The lower part of the cylinders is formed by extending three of the outer cylinders to the bottom, and the cylinders are connected by several layers of heave plate structures, which meet the strength requirements of the main body and increase the added mass and damping. Ballast tank is also placed at the bottom of these cylinders to ensure adequate stability of the platform. The application of cylinders with smaller diameter makes it easy for construction, but also brings the challenge of welding heave plates in a uniform way (Fig. 3).

Other Concept of Spar Platforms

There are some other types of Spar platforms that have been proposed and constructed, and they are listed as below.

1. The Min Doc (Minimum Deepwater Operating Concept) platform was first used by the ATP Oil and Gas Development Company in the

SPAR Platform, Fig. 3 Cell Spar

Gulf of Mexico in 2009 and installed in the depth of 1219 m in the Telemark Hub block.

2. The Single Column Floater (SCF) concept is similar to the Spar platform. Its structure can be divided into the upper module, the platform body, and the riser and mooring system, as shown in Fig. 4.
3. Combining the characteristics of the Truss Spar and multicolumn Spar platforms, the concept of the TCell Spar platform is also proposed.

Dry Tow Operation

Dry tow is an important offshore operation, especially for Spar and TLP platforms. Non-self-propelled offshore equipment such as drilling platforms, pipe-laying vessels, and living platforms are costing hundreds of millions of dollars, weighing 10,000 tons and extending as long as several hundred meters. These extremely large

SPAR Platform, Fig. 4 Other concepts of Spar platforms: (a) The MinDoc platform, (b) SCF, (c) TCell platform

pieces have to be towed from the land manufacturing base to the ocean or from one operation area to the other area for ocean transportation. Dry tow is a large-scale structure transportation method commonly used in offshore engineering field. However, due to the long towing time on the sea, the meteorological conditions, possible severe sea conditions, and technical conditions of the navigations, dry towing transportation is still relatively difficult and risky. Safe and reliable dry tow transportation requires not only reliable hard power support but also strong, mature support of soft power.

Generally speaking, long-distance transportation for large-scale offshore platforms such as Spar and TLP are adopting dry tow and wet tow both. Dry tow is to load the floating offshore platform on a semi-submersible ship and transport it. Figure 5 shows the dry tow process of a Spar platform on a semi-submersible ship.

During the dry tow operation process, engineers need to design two processes. One process is to tow the Spar or TLP platform onto the semi-submersible ship at the dock area, and the other process is separate TLP or Spar platform away

from the semi-submersible ship after they arrive at the operation sea site.

The process of towing Spar or TLP platform onto semi-submersible ship deck is a critical process. In the process of transferring Spar or TLP platform onto the semi-submersible ships, a good weather window is more conducive to execute operations, and it generally needs to consider various environmental conditions such as tidal variation, wind speed, and surge flow rate. Among these environmental factors, tidal variation is of the most importance, and it must be included in the design.

Upending Operation

As the spar platform becomes more widely used, the performance of the spar platform during transportation, construction, and installation needs to be noticed. When the SPAR platform is sent to the installation location, it needs to be righted, that is, the process of changing it from a horizontal status to a vertical status. The load on the motion and structure of the spar platform during the upending process is completely different from that of the

SPAR Platform,

Fig. 5 Dry tow of a spar.
(Picture from www.offshore-technology.com)

SPAR Platform, Fig. 6 The whole process of spar platform upending: (a) The starting moment (b) The middle moment (Picture from www.equinor.com). (c) The final moment. (Picture from www.statoil.com)

spar platform during its normal operation. The process of upending is achieved by injecting water into the ballast tank, which starts from the tank near the bottom of the spar platform.

The induced motions and loads during the upending process are of great importance to be checked. At the beginning of the upending, the slowly injected water broke the hydrostatic

moment balance of the horizontally floating spar platform on the water surface, and the bottom of the spar platform began to sink, forcing the spar platform to begin to slowly right up. The joint of the truss will bear a large total longitudinal bending moment, which is a severe test for the structural strength of the platform. Therefore, the main longitudinal bending moment of the joint between the hard chamber and the truss during the upending process needs to be focused on. In addition, the movement of the platform during the upending process also needs attention, such as the platform's six-DOF motions. The surge and sway motions have an important impact on the construction safety of the upending process. Meanwhile, the pitching motion of the platform is related to the success of the upending process. What's more, the platform's heave motion has a great influence on the stability of the platform during the upending process (Fig. 6).

Definition

Spatial variability refers to the phenomenon that a quantity that is measured at different spatial locations exhibits values that differ across the locations.

Scientific Fundamentals

Sources and Engineering Influences of Spatial Variability

Natural materials (such as soil, rock, water, and air) often possess physical properties (such as density, strength, conductivity) that are associated with spatial variability. This is because the natural materials have been formed by a combination of various geologic, environmental, and physical-chemical processes that are themselves random processes in time and space. Many of these processes are continuing and can be modifying the natural materials in situ. As a result, the physical properties of natural materials display complex patterns of variation in space – in two or three dimensions – as well as variation with time. The variability may be small or large. There is a greater tendency for the properties to be similar in value at closely neighboring points than at widely spaced points because neighboring materials are more likely to have gone through similar natural processes during their formations. Spatial correlation length (or scale of fluctuation), θ , is

often used to quantify the correlation structure of spatially varying property. It provides an indication of the distance within which the property values show relatively strong correlation. A large θ implies that the properties fluctuate slowly with distance, while a small θ implies that the fluctuation is very rapid. The correlation length is usually direction-dependent. For example, soil properties usually have a smaller correlation length in vertical direction than in horizontal direction due to the deposition process which causes the soil properties to vary more significantly in vertical direction (Phoon and Kulhawy 1999).

Spatial variability of the properties of natural materials can pose significant influences on the evaluation of the performance and reliability of any engineering system built on, in, or with natural materials. Neglecting the spatial variability sometimes can lead to an unconservative estimation of the safety status of an engineering system. For example, Griffiths and Fenton (2004) found that the failure probability of a slope can be underestimated if the spatial variability of soil strength parameters is not considered. Therefore, the spatial variability needs to be rationally characterized and considered in the analysis of engineering systems for at least three purposes:

1. Characterizing the engineering system with spatially varying parameters
2. Predicting the response (behavior, performance, sustainability) of the engineering system
3. Providing basis for engineering decisions (in design, maintenance, or dynamic control)

Spatial variation of the natural material properties is essentially of a passive type. The material property at a given location is deterministic, but its value is unknown until accurately measured. Sampling at all locations is usually impractical and uneconomical, and measurement and testing errors tend to dilute the value of the information (Vanmarcke 1984). Therefore, the tasks of prediction, analysis, and decision-making must usually proceed on the basis of incomplete information about the spatially varying material properties,

and this fact requires a robust and effective technique to model the spatial variability.

Random Field Modeling of Spatial Variability

Spatial variability is usually decomposed into a smoothly varying trend $T(l)$ and a residual variation about the trend $R(l)$ as follows:

$$P(l) = T(l) + R(l) \quad (1)$$

where $P(l)$ is a spatially varying property and l is the location. The trend is modeled by a deterministic function obtained by regression analysis. The residuals are correlated and represent the inherent spatial variability. The most commonly used method to quantify the inherent variability is to model $R(l)$ by a homogeneous random field (Vanmarcke 1984). A random field is called homogeneous if (1) $R(l)$ shares the same mean and standard deviation across all locations and (2) the correlation among $R(l)$ at two different locations depends only on their separation distance rather than their absolute locations. These conditions are usually satisfied if the data are detrended and extracted from a homogeneous material. The correlation structure of a random field is usually described by a correlation matrix C as:

$$C_{ij} = \rho(\tau_{ij}) \quad (2)$$

where τ_{ij} is the separation distance between locations l_i and l_j and $\rho(\cdot)$ is the autocorrelation function denoting the correlation coefficient among $R(l)$ at two different locations separated by τ_{ij} . If there is enough field data, $\rho(\tau_{ij})$ can be estimated by a statistical analysis. However, in most cases, field data is limited. Therefore, it is more common to use the limited field data to fit a theoretical autocorrelation function. Table 1 summarizes the frequently used autocorrelation functions. The correlation structure is important for improving estimates at unsampled locations. Aside from the correlation structure, the mean (μ) and standard deviation (σ) of the inherent variability are also basic parameters of a random field model. If the

Spatial Variability, Table 1 Commonly used autocorrelation functions

Type	1-D autocorrelation function	Scale of fluctuation	2-D autocorrelation function
Triangular	$\rho(\tau) = \begin{cases} 1 - \tau/e & \text{for } \tau \leq e \\ 0 & \text{for } \tau > e \end{cases}$	$\theta = e$	$\rho(\tau_x, \tau_y) = \begin{cases} \left(1 - \frac{\tau_x}{\theta_h}\right)\left(1 - \frac{\tau_y}{\theta_v}\right) & \text{for } \tau_x \leq \theta_h \text{ and } \tau_y \leq \theta_v \\ 0 & \text{for others} \end{cases}$
Exponential	$\rho(\tau) = \exp(-\tau/a)$	$\theta = 2a$	$\rho(\tau_x, \tau_y) = \exp\left[-2\left(\frac{\tau_x}{\theta_h} + \frac{\tau_y}{\theta_v}\right)\right]$
Second-order autoregressive	$\rho(\tau) = \exp(-\tau/c)(1 + \tau/c)$	$\theta = 4c$	$\rho(\tau_x, \tau_y) = \exp\left[-4\left(\frac{\tau_x}{\theta_h} + \frac{\tau_y}{\theta_v}\right)\right]\left(1 + \frac{4\tau_x}{\theta_h}\right)\left(1 + \frac{4\tau_y}{\theta_v}\right)$
Gaussian	$\rho(\tau) = \exp[-(\tau/b)^2]$	$\theta = \sqrt{\pi}b$	$\rho(\tau_x, \tau_y) = \exp\left[-\pi\left(\frac{\tau_x^2}{\theta_h^2} + \frac{\tau_y^2}{\theta_v^2}\right)\right]$
Exponential-cosinoidal	$\rho(\tau) = \exp(-\tau/d) \cos(\tau/d)$	$\theta = d$	$\rho(\tau_x, \tau_y) = \exp\left[-\left(\frac{\tau_x}{\theta_h} + \frac{\tau_y}{\theta_v}\right)\right] \cos\left(\frac{\tau_x}{\theta_h}\right) \cos\left(\frac{\tau_y}{\theta_v}\right)$

Note: θ_h and θ_v are the scales of fluctuation in the horizontal and vertical directions, respectively; τ_x and τ_y are the horizontal and vertical distances between two locations, respectively

homogeneous conditions are satisfied, the mean of $R(I)$ is a constant value of zero because it is fluctuating equally about the trend. The standard deviation can be evaluated by the field data as:

$$\sigma = \sqrt{\frac{1}{n-1} \sum_{i=1}^n [R(I_i)]^2} \quad (3)$$

where n is the number of data points and $R(I_i)$ is the residual at location I_i .

With the mean, standard deviation, and the correlation structure, a random field can be generated to model the spatial variability. A variety of methods of generating random fields are available, including the local average subdivision method, covariance matrix decomposition, fast Fourier transformation, and the turning-band method. In the following, the covariance matrix decomposition method is introduced. Readers who are interested in other random field generation methods can refer to Fenton and Griffiths (2008). The covariance matrix decomposition method involves three steps:

1. Decompose correlation matrix C into the product of a lower triangular matrix and its transpose by Cholesky decomposition:

$$C = LL^T \quad (4)$$

2. Generate a standard Gaussian random field G :

$$G = LU \quad (5)$$

where U is a vector of independent standard normal random variables.

3. Transform the standard Gaussian random field into the target random field based on the mean, standard deviation, and the probability distribution of the target field. For instance, if the target random field $R(I)$ follows a lognormal distribution, it can be obtained by:

$$R(I) = \exp(\lambda + \xi G) \quad (6)$$

$$\xi = \sqrt{\ln[1 + (\sigma/\mu)^2]} \quad (7)$$

$$\lambda = \ln(\mu) - 0.5\xi^2 \quad (8)$$

Figure 1 shows a random field realization of the spatially varying strength parameter (q_c) of a two-layer soil (Li et al. 2018). The spatial variability is well characterized by the random field.

To evaluate the impact of spatial variability on the responses of an engineering system, random field simulations are usually integrated within a Monte Carlo simulation framework in a probabilistic manner. Let F denote the response of a system, e.g., factor of safety, deformation, etc. F is a function of $R(I)$:

$$F_i = f(R_i(I)) \quad (9)$$

where $R_i(I)$ is the i th realization of the random field and F_i is the value of F in the i th simulation.

Spatial Variability,

Fig. 1 A random field realization of the spatially varying strength parameter (q_c) of a two-layer soil (Li et al. 2018)

By generating a large number of random field realizations and repeatedly calling Eq. (9), one can obtain sufficient data of the response. Afterward, statistical analysis can be conducted to evaluate the quantities of the response such as the mean, standard deviation, and the probability distribution type, which can be used to assess the response of the system considering the spatial variability of the parameters.

Key Applications

Characterization of Spatial Variability

To characterize the spatial variability of a seabed soil, the trend, autocorrelation function, and scale of fluctuation should be investigated. Baecher and Christian (2003) presented the methods to characterize spatial variability. Generally the characterization consists of four steps (Lacasse et al. 2014): (a) visual inspection of data by soil unit and preliminary second-moment data analysis, (b) identification of a deterministic trend function and decomposition, (c) identification of a suitable uncertainty model, and (d) quantification of the uncertainty (mean, variance, standard deviation, scale of fluctuation).

The spatial variability of seabed soils has been reported for the North Sea, the Gulf of Mexico, offshore Australia, etc. It is found that the undrained shear strength (s_u) of clay followed a normal or lognormal distribution with its

coefficient of variation (COV) ranging between 5% and 35%. Uzielli et al. (2006) analyzed the cone resistance of Troll clay off the shore of Norway and reported that the undrained shear strength increased with depth. The mean value of the Troll clay increased from 12.7 kPa to 36.3 kPa with its standard deviation increasing from 2.0 kPa to 5.3 kPa. Bienen et al. (2011) found that the COV of offshore soils varied between 2% and 41% with a mean value of 23% based on data from 14 offshore clay sites. The spatial variation of the seabed soils was investigated using random field theory. The scale of fluctuation of the undrained shear strength and cone penetration resistance are reviewed and summarized in Table 2 (Li et al. 2016b). The vertical scale of fluctuation ranges from 0.05 m to 14 m. The scale of fluctuation in the horizontal direction varies over a large range from 7 m to 9000 m, which is much larger than that in the vertical direction.

Properly accounting for the spatial variability in seabed soils may reduce substantially the uncertainties in soil parameters and the uncertainties associated with a design. Unfortunately, one is never able to gather enough subsurface data to get an exact picture of the variation of a soil property. One must therefore interpolate the soil properties within a large volume. A stochastic interpolation technique that can account for the spatial variability and minimize the variance is the kriging approach (Matheron 1963; Nadim 1988).

Spatial Variability, Table 2 Scales of fluctuation for offshore soils (Li et al. 2016b)

Soil	Location	Property	Scale of fluctuation (m)		Reference
			Horizontal	Vertical	
Offshore soils	North Sea	Cone penetration resistance	35.4–62	–	Tang (1979)
Sand	North Sea	Cone penetration resistance	26	0.4	Wu et al. (1987)
Offshore soils	–	Cone penetration resistance	24.6–66.5	–	Keaveny et al. (1989)
Offshore soils	–	Undrained shear strength	–	0.48–7.14	Keaveny et al. (1989)
Silty clay	North Sea	Cone penetration resistance	7–24	1.4–2.0	Lacasse and Lamballerie (1995)
Clay	Norwegian trench	Undrained shear strength	–	0.05–0.08	Uzielli et al. (2006)
Offshore soils	Gulf of Mexico	Undrained shear strength	9000	14	Cheon and Gilbert (2014)
Clay	Timor Sea	Cone penetration resistance	317	–	Li et al. (2015a)

Spatial Variability,

Fig. 2 Predicted net penetration resistance using kriging interpolation technique (units of kPa; Li et al. 2015a)

Li et al. (2015a) presented the spatial variability of seabed soils for the Laminaria site in the Timor Sea between Australia and Indonesia. There are only seven piezocones and six T-bar penetrometer tests in this site. A kriging method was presented to estimate the net penetration resistance at locations of interest, which further facilitated the evaluation of the spatial variability. Figure 2 shows the estimated values as a contour map of the net penetration resistance along with the measured data of the site. The predictions indicate that the net penetration resistance is larger in the central part of the site. This prediction provides enough data to evaluate the spatial variability of the seabed soils. A single exponential function was observed to best fit the autocorrelation data, and, subsequently, the horizontal scale of fluctuation for these data is estimated to be 317 m. The kriging interpolation technique was used to interpolate rock depth (Dasaka and Zhang 2012) and soil stratification (Li et al. 2016a).

Spudcan Response in Spatially Variable Seabed Soil

Mobile jack-up platforms are key contributors to the development of offshore oil and gas reservoirs in shallow to moderate water depths. A jack-up is self-installed by lifting the hull from the water and pushing the large spudcans (approximately 20 m in diameter) into the seabed. The influence of the spatially varied properties of seabed soils on the bearing capacity of the embedded spudcan

foundation is studied by Cassidy et al. (2013) and Li et al. (2015b). To simulate the spatial variability of the seabed soils, the undrained shear strength of clay was modeled as a random field. Random fields are mapped into a nonlinear finite-element analysis to reveal the failure mechanisms of the spudcan in spatially varied soils.

Random fields of undrained shear strength were generated using the local average subdivision algorithm. Finite-element analyses were performed using the nonlinear finite-element software ABAQUS 6.11. The soil domain was discretized into many zones onto which the random field of undrained shear strength was mapped. The soil properties vary from zone to zone to reflect the spatial variability of the soil. Monte Carlo simulations were performed for considerable realizations of the soil random field and the subsequent finite-element simulations. For each analysis, the bearing capacity of a spudcan foundation increases with increasing applied displacement until plateauing at the failure value, which is termed the ultimate bearing capacity. The results are presented in terms of the bearing capacity factor N_c for each realization:

$$N_c \frac{q_i}{\mu_s} \quad (10)$$

where q_i is the bearing pressure computed for the i th realization in each case and μ_s is the mean value of the undrained shear strength.

Results show that the ultimate bearing capacity of the spudcan varies significantly with the spatial variation of the seabed soils. Figure 3 shows the change in the bearing capacity factor for random fields with a horizontal scale of fluctuation of 54 m and a vertical scale of fluctuation of 3 m. The mean bearing capacity factor is 10.72, which is smaller than that of the uniform soil (e.g., 11.82). The bearing capacity factors in 93% of the random cases are smaller than that in the uniform soil. The worst cases occur when a localized failure path easily forms in the weak soils. When layers of strong soils around the foundation hinder the development of a continuous shear path, a relatively large bearing capacity can occur.

When the scale of fluctuation in the vertical direction is large, the correlation is strong for a relatively large volume of soils, as shown in Fig. 4. If a foundation is encompassed by a large volume of weak soils, a shear plane is developed locally in the weak soils (Fig. 3a).

Hence, the resistance is limited by the relatively small influential soil volume and the small undrained shear strength. In contrast, if a foundation is surrounded by a large volume of strong soils, the shear plane tends to develop in far-away weak soils, and a large volume of soils is thus mobilized, as shown in Fig. 3b. This long shear plane, combined with the large shear strength along the path, leads to a large bearing capacity in this realization. Therefore, the discrepancy in different realizations can be significant for cases with large scales of fluctuation. As the vertical scale of fluctuation decreases from 54 m to 3 m, the variation in the shear strength in the vertical direction becomes intensive, as shown in Fig. 3c, d. The shear planes pass through both the weak soils and strong soils in each realization, which result in similar bearing capacities. Hence the spatial variability of seabed soils significantly affects the bearing capacity of foundations.

Spatial Variability, Fig. 3 Distribution of the ultimate bearing capacity factor for the spudcan foundation

Spatial Variability, Fig. 4 Shear planes for selected realizations of Case II and Case V: (a) Realization No. 48 of Case V ($N_{cu} = 6.15$); (b) Realization

No. 400 of Case V ($N_{cu} = 21.15$); (c) Realization No. 355 of Case II ($N_{cu} = 9.79$); (d) Realization No. 201 of Case II ($N_{cu} = 10.74$) (Li et al. 2016b)

Dalian, China

Definition

The term “special marine vehicle” here is intended to encompass all the classifications that are not

clearly included in other categories of this book. In other words, it is more like the “miscellaneous” of all the surface and underwater marine vehicles.

Scientific Fundamentals

Basic Type

Unmanned Surface Vehicle (USV)

Unmanned surface vessels (USVs) have also been called autonomous surface craft (ASC). As the name implies, they remove the operators from the platform and allow new modes of operations (Manley 2008) based on innovations in high-payload, high-speed small craft design and unmanned systems technology. USVs extend the success of autonomous underwater vehicle to surface vehicle, which could provide safer and cheaper choice to meet the various civil and military demands.

USVs are used by academic labs, corporations, and government users (Manley 2008). Typical applications include environment monitoring and survey, bathymetric mapping, object searching, general robotics research, etc.

Leisure and Sports Ships

The most common type of leisure ships worldwide is called “yacht.” There are two different classes of yachts: sailing and power boats. Sailing boat is the boat for which the primary means of propulsion is wind power. With the rise of the steamboat and other types of powerboat, sailing vessels in general came to be perceived as luxury or recreational vessels. Later the term came to encompass large motor boats for primarily private pleasure purposes as well.

Rowing boat, which is propelled by using the motion of oars in the water, displacing water, and moving the boat forward, is another common type of ships for recreational or sports purpose. There are two ways of connecting oars with ships, i.e., paddling and rowing. Rowing requires oars to have a mechanical connection with the boat, while paddles are handheld and have no mechanical connection.

Engineering Vessels/Ships

The concept of the engineering ship is usually defined as the ship that are equipped with various corresponding special equipment or engaged in various engineering and technical services for the requirements of different engineering operations. It has numerous types and complex equipments. And it has strong professionalism, which applies more new technologies and new equipments with different characteristics.

Icebreaker

An icebreaker is a special-purpose ship or boat designed to move and navigate through ice-covered waters and provide safe waterways for other boats and ships. For a ship to be considered an icebreaker, it requires three traits that most normal ships lack: a strengthened hull, an ice-clearing shape, and the power to push through sea ice. In the ice-covered region (e.g., the Baltic Sea, etc.), the main functions of icebreakers include escorting ships safely through ice-filled waters or freeing immobilized ship surrounded by ice. In difficult ice conditions, the icebreaker can also tow the weakest ships. As offshore drilling moves to the Arctic seas, icebreaking vessels are needed to supply cargo and equipment to the drilling sites and protect the drillships and oil platforms from ice by performing ice management. In the past, such operations were carried out primarily in North America, but today Arctic offshore drilling and oil production are also going on in various parts of the Russian Arctic (Riska 2011; Segercrantz 1989).

Rescue and Repair Ships

Rescue ships are a type of salvage vehicle. They are tasked with searching and rescuing lives and salvage property in wartime or in peacetime (Małyszko and Wielgosz 2016). Rescue ships are required to be robust enough to provide assistance in maritime accidents, such as combat salvage, rescue towing, firefighting, emergent repair, ocean towing, and heavy lift (Southworth 2008). The Navy designed the first seagoing “tug” the NAVAJO (ATF-64) class in 1939, to support logistic requirements for World War II.

A repair ship is a naval auxiliary ship designed to provide maintenance support to warships. Repair ships provide similar services to destroyer, submarine and seaplane tenders, or depot ships but may offer a broader range of repair capability including equipment and personnel for repair of more significant machinery failures or battle damage.

Key Applications

Basic Type

Unmanned Surface Vehicle (USV)

Military Uses USVs have the potential to reduce risk to manned forces; provide the necessary force to accomplish reconnaissance and patrolling missions (Bertram 2008; Caccia et al. 2007), search and rescue, and anti-terrorism/force protection (Pastore and Djapic 2010); perform tasks which manned vehicles cannot; and do so in a way that is affordable for the navy. Figure 1 shows an example of the weapon-loaded USV patrolling in Persian Gulf.

Environmental Sciences For the civil purposes, USVs are designed primarily for oceanographic surveys (Campbell et al. 2012), seafloor mapping, environmental monitoring, platform to predict natural disasters, and undertaking pollutant

Special Marine Vehicle, Fig. 1 An operational weapon-loaded USV deployed for maritime security and defense in the Persian Gulf (Bertram 2008)

Special Marine Vehicle, Fig. 2 Springer USV developed by Marine & Industrial Dynamic Analysis Research Group (MIDAS) at the University of Plymouth (Naem et al. 2006)

tracking and cleanup in rivers, reservoirs, inland waterways, and coastal waters, particularly where shallow waters prevail. Figure 2 shows a USV for environmental monitoring.

Commercial Exploitation USVs are developed to play a key role in future hydrocarbon exploration and exploitation, such as oil, gas, and mine explorations (Pastore and Djapic 2010), offshore platform/pipeline construction, and maintenance (Bertram 2008). The use of USVs can contribute to reduced personnel costs, improved personnel safety, widened weather window of operations, increased operational precision, and more environmentally friendly activities (Breivik et al. 2008). Figure 3 shows an industrial-level USV which is designed for target tracking.

Leisure and Sports Ships

Yacht The length of a yacht normally ranges from 10 m up to dozens of meters. A luxury craft smaller than 12 m is more commonly called a cabin cruiser or simply a cruiser. A superyacht generally refers to any yacht (sail or power) above 24 m, and a megayacht generally refers to any yacht over 50 m. The size of a yacht is small in relation to typical cruise liners and oil tankers (www.merriam-webster.com). Figures 4 and 5 show typical cruiser and megayachts, respectively.

Special Marine Vehicle, Fig. 3 An industrial-level USV developed by Rafael of Israel (<https://en.wikipedia.org>)

Special Marine Vehicle, Fig. 4 The “Lazzara” 80’ “Alchemist” on the California Coast (<https://commons.wikimedia.org>)

Windsurfing Windsurfing (as shown in Fig. 6) refers to the use of sail power to ride a rudderless, no-cabin boat to make a water sport. It consists of a board usually 2.5–3 m long, with displacements typically between 60 and 250 l. As a water sport project between sailing and surfing, the windsurfing consists of a plate with a steady plate, a gimballed mast, a sail, and a sail rod. Athletes use the natural wind blowing on the sails, stand on the board, operate the sails through the sail levers, and make the speed of the valve plate run on the water surface.

Dragon Boat As shown in Fig. 7, it is a long and slender rowing boat with a dragon’s head at its bows, used for racing with a mixed crew (Ayto and Crofton 2006). It has its roots in an ancient

Special Marine Vehicle,**Fig. 5** Motor yacht Samar

(<https://commons.wikimedia.org>)

Special Marine Vehicle, Fig. 6 Windsurfing (<http://www.toopen.com>)

folk ritual of contending villagers, which has been held for over 2000 years throughout southern China (https://en.wikipedia.org/wiki/Dragon_boat). It is also one of a family of traditional paddled long boats found throughout Asia, Africa, the Pacific Islands, and also Puerto Rico.

Engineering Vessels/Ships

Dredger Dredgers are responsible for digging waterways and river silt to facilitate the passage of other ships. And they can also be used for sand reclamation. At present, dredgers mainly include cutter suction dredgers (fighting bucket dredgers), trailing dredgers, chain bucket dredgers,

grab dredgers, and shovel dredgers (Qian 2008). Figure 8 shows the cutter suction dredger “Tian Jing Hao.”

Piling Vessel The piling vessel (the middle ship as shown in Fig. 9) is used for piling operations on the water. There is a piling frame at the end of the deck, which can bend forward and backward to meet the needs of the battered pile. The piling boat is a non-self-propelled ship and is towed in place by pushing (towing) wheels (near bow and stern of the dredger in Fig. 9). With the continuous enlargement of the scale of the port construction and the deepwater development of the offshore engineering, the performance requirements of the engineering operations on the piling vessel have also continuously increased.

Crane Vessel A crane vessel, crane ship, or floating crane is a ship with a crane specialized in lifting heavy loads. The crane vessels are generally used for offshore construction. Conventional monohulls are used, but the catamaran or semisubmersible-type crane vessels are often larger as they have increased stability. On a sheer leg crane, the crane is fixed and cannot rotate, and the vessel therefore is maneuvered to place loads (https://en.wikipedia.org/wiki/Crane_vessel). Figure 10 shows a typical crane vessel for offshore construction.

 dredger (<http://img1.voc.com.cn>)

Pipe-Laying Vessel Pipe-laying vessel is the main equipment for the development and construction of deepwater oil and gas fields and is also responsible for the installation of floating production platforms laying of submarine pipelines and installation of riser system. The main methods of pipe laying in deep water are S-lay, J-lay, reel lay and carousel lay, and vertical lay (Huang et al. 2011; Leffler et al. 2003; Gerwick 2007). Figure 11 shows a vertical lay-type vessel.

Icebreaker

Steam-Powered Icebreakers The first true modern seagoing icebreaker (Record 1951) was built at the turn of the twentieth century. Icebreaker Yermak (as shown in Fig. 12) was built in 1897 at the Armstrong Whitworth naval yards in England under contract from the Russian Navy. The ship borrowed the main principles from Pilot and applied them to the creation of the first polar icebreaker, which was able to run

Special Marine Vehicle,**Fig. 9** Piling vessel (<http://www.kinca.cn>)**Special Marine Vehicle,****Fig. 10** Crane vessel (<http://i.ce.cn>)

over and crush pack ice. The ship weighed 5000 tons, and its steam-reciprocating engines delivered 10,000 horsepower. The ship was so well built that it was only finally decommissioned and scrapped in 1963, making it one of the longest serving icebreakers in the world.

At the beginning of the twentieth century, several other countries began to operate purpose-built icebreakers. Most were coastal icebreakers, but

Canada and Russia also built several oceangoing icebreakers of around 10,000 t displacement.

Diesel-Powered Icebreakers Diesel-powered icebreakers are the mainstream form. The world's first diesel-electric icebreaker was the Swedish icebreaker Ymer in 1933, which was followed by the Finnish Sisu, the first diesel-electric icebreaker in Finland, in 1939 (Koehler and Oehlers

Special Marine Vehicle,

<http://www.cnss.com.cn>

Special Marine Vehicle,
Fig. 12 Yermak, the first
 modern polar icebreaker
<https://en.wikipedia.org>

1998). Both vessels were decommissioned in the 1970s and replaced by much larger icebreakers in both countries, the 1976-built Sisu in Finland and the 1977-built Ymer in Sweden.

In the United States, the need of research in Scandinavia and the Soviet Union led to the design of Wind-class icebreaker in 1941, which had a very strongly built short and wide hull, with a cut away forefoot and a rounded bottom. Powerful diesel-electric machinery drove two stern and one auxiliary bow propeller (Preston

1998; Silverstone 1970). These features would become the standard for postwar icebreakers until the 1980s. Figure 13 shows the USCGC Healy, which became the first unaccompanied US surface vessel to reach the North Pole in 2015.

In Canada, the first diesel-electric icebreaker HMCS Labrador started to be built in 1952. Then in 1969, Canada's largest and most powerful icebreaker, the 120-m CCGS Louis S. St-Laurent, was delivered. A multi-year mid-life refit project (1987–1993) saw the ship get a new bow and a

wikipedia.org](https://en.wikipedia.org))

new propulsion system. On August 22, 1994, Louis S. St-Laurent and USCGC Polar Sea became the first North American surface vessels to reach the North Pole.

Nuclear Icebreakers Russia currently operates all existing and functioning nuclear-powered icebreakers. The first one, NS Lenin, was launched in 1957 and entered operation in 1959, before being officially decommissioned

in 1989. It was both the world's first nuclear-powered surface ship and the first nuclear-powered civilian vessel.

The second Soviet nuclear icebreaker was NS Arktika (Fig. 14), the lead ship of the Arktika class. In service since 1975, she was the first surface ship to reach the North Pole, on August 17, 1977.

In May 2007, sea trials were completed for the nuclear-powered Russian icebreaker NS

50 Let Pobedy. The vessel was put into service by Murmansk Shipping Company, which manages all eight Russian state-owned nuclear icebreakers. The keel was originally laid in 1989 by Baltic Works of Leningrad (now St Petersburg), and the ship was launched in 1993 as the NS Ural. This icebreaker was intended to be the sixth and last of the Arktika class and currently is the world's largest icebreaker.

Rescue and Repair Ships

Deep-Submergence Rescue Vehicle A deep-submergence rescue vehicle (DSRV) is designed for immediate rescue operation in the incident for submarine mishap (Auxillia 2017). While DSRV is the term most often used by the US Navy, other nations have different designations for their vehicles. In a rescue mission, they are capable of searching for and rescuing life by themselves after transported to the submarine area by lifeboat or submarine ship. Figure 15 shows the submarine rescue diving recompression system.

Convoy Rescue Ship Convoy rescue ship (as shown in Fig. 16) is designated convoy rescue ships which accompanied some Atlantic convoys

to rescue survivors from ships that had been attacked. Rescue ships were typically small. They were usually stationed at the rear of the center column of the convoy.

Self-Propelled Semisubmersible Repair Ship Referring to the technology of floating ship, maintenance ship, and related engineering ship, a self-propelled semisubmersible repair ship (as shown in Fig. 17) is built on the basis of semisubmersible ship (Gou 2015). They are regarded as ship maintenance platform floating on the sea. Their task is transport of large goods, salvage, and reducing maintenance time.

Offshore Subsea Pipeline Maintenance Vehicle (SPMV) A SPMV is a type of special underwater vehicle which can navigate under the water, automatically detect and track the submarine pipeline and accurately locate the seabed, and carry out the inspection and maintenance of the pipeline (Li 2008). SPMV includes complete power machinery, propulsion, and manipulating equipments and is also equipped with full monitoring and maintenance equipments. They are tasked with survey of submarine pipeline, inspection of laid cable, and maintenance of submarine pipeline and laid cable.

Spread Mooring System

Yong Luo

Shanghai Jiao Tong University, Shanghai, China

Synonyms

Multiple line moorings; Offshore mooring system; Single-point moorings; Station-keeping system

Definition

The passive mooring is the most commonly adapted station-keeping method for offshore floating facilities. An offshore mooring system usually consists of one or multiple mooring lines that connect the floater to the seabed to retain floater's position and limit offset to enable designated operations in various environments and water depths. There are two main categories of offshore mooring systems. The single point mooring system with mooring lines connected to the point of rotation of the floater such that it only restrain the floater position while allowing weather vanning. The spread mooring system utilizes multiple spread mooring lines connected to the multiple

Spread Mooring System, Fig. 1 Typical spread mooring system. (Courtesy of Vryhof)

locations of the floater to restrain its position as well as heading. For both types of mooring systems, the mooring line is usually made up of chain, wire rope, polyester, anchor, and connectors. In the spread mooring system, all mooring lines are pretensioned to form catenary or taut-leg profile and spread out in all directions (Fig. 1).

Historical Development

The mooring system can trace its origin to navigation. As ships sail around the world, the anchor mooring holds vessel's position relative to a point on the seabed of a waterway without connecting the vessel to shore. As such, mooring lines have been used for station-keeping of floating vessels in various situations. For example, they are used to berth boats or ships at quaysides, and often referred to as quayside moorings. In association with the development of offshore oil and gas exploration, the spread mooring system was further developed for station-keeping of various offshore platforms for operations of drilling, production, pipe laying, workover, etc.

Oil and gas have been produced offshore since the late 1940s. Bottom-founded structures such as fixed platforms were initially used for shallow-water operation. As exploration and production

moved to deeper waters and more distant offshore locations, the number of floating production systems increased, which utilized the spread mooring systems for station-keeping.

The first mobile offshore drilling unit (MODU) was the Mr. Charlie. It was a submersible barge built specifically to float on its lower hull for transportation to the location. It had to run a sequence of ballasting in order to rest on the bottom to begin drilling operations in 1954 (Veldman and Lagers 1997). It was rated for 40-ft water depth, even though strictly speaking, it was not floating during the drilling operation.

The first semisubmersible floating production platform was the Argyll FPF converted from the Transworld 58 drilling semisubmersible in 1975 for the Hamilton Brothers Argyll oil field in the North Sea. The SPAR platform was developed in later years as offshore production moves further into deeper waters. The first spar was the Neptune spar installed in 1997 in GOM. The first FPSO was the Shell Castellon, built in Spain in 1977 (Jay Schempf 2007).

Principles of Spread Mooring System

Mooring Functions

The functions of the mooring system can be summarized as:

1. To maintain the floating structure on station
2. To have sufficient strength and fatigue life reserves to guarantee the safety and operability
3. To limit the excursion of the floater for the sake of risers and umbilicals, and maintaining adequate clearance with adjacent facilities

Mooring Spread

In a typical spread mooring system, the floating platform maintains the station-keeping by groups of mooring lines that connect the hull with anchors on the seabed. The mooring lines are spread out so that platform's lateral movement as well as the heading is restrained. The number of mooring lines and their lengths and dimensions depends on the environment and water depth at the location.

A typical spread mooring system can have a minimum of three mooring lines to as many as say 36 or even more lines. As a rule of thumb, the number of lines should be kept to a minimum as fewer lines; fairleads/winches mean less material costs and less installation time. However, as the number of lines reduces, the required line size for a given mooring system increases accordingly that would cause difficulty in line fabrication and installation.

The selection of mooring spread pattern should consider a number of factors such as system engineering, installation, directionality of environment, and mooring material cost. The equal spread design in which all mooring lines are spread symmetrical with equal spread angles has been used for ease of design and installation. Often the mooring lines are symmetrically grouped into three or four groups to improve the mooring system performance and create space for risers and other subsea facilities (Fig. 2).

Spread Mooring System, Fig. 2 Mooring line spread

Spread Mooring System, Fig. 3 Catenary mooring system. (Courtesy of Vryhof)

The mooring design typically has symmetrical design, i.e., all mooring lines are of the same composition and spread symmetrically with regards to direction. In some cases, the designer would take advantage of the directionality of the environment or the riser bundle to layout the mooring pattern in a nonsymmetric way. The use of a noneven spread or a nonuniform anchor radius can reduce the mooring system cost but may increase the engineering and installation efforts.

Mooring Line Configuration

According to the mooring line configuration, the mooring system can be further divided into **catenary mooring system** (Fig. 3) and **taut-leg mooring system** (Fig. 4).

The catenary mooring system is the most commonly used system in shallow water. It gets its name from the shape of the free-hanging catenary line as its configuration changes due to vessel offset and motions. As shown in the figures below, the weight of the mooring material forms a catenary line shape of mooring legs, and during dynamic responses the catenary mooring system has a line profile that is part of the mooring line lying on the seabed in the static equilibrium position. The catenary mooring system uses more line material for the sake of compliance to floater offset and motion.

The taut-leg mooring system has no line lying on seabed in the static equilibrium position, and the mooring lines are naturally taut from anchor to seabed to the fairlead on the floater. The taut leg

Spread Mooring System,

Fig. 4 Taut-leg mooring system. (Courtesy of Vryhof)

system may use wire rope or polyester rope that is pretensioned until taut. The rope comes in at a 30–45° angle on the seabed where it meets the anchor (suction piles or vertically loaded anchors), which is loaded vertically. When the platform offsets horizontally with wind, waves and current, the lines stretch, and this generates the so-called restoring force.

The anchor footprint of such a mooring system is smaller and also the system uses less line material compared to the catenary mooring system. However, as the lines are taut, the compliance to floater offset and dynamic response is mostly from the line tensile stretch which is only possible in deep or ultra-deep waters where the mooring lines are sufficiently long.

The semitaut system combines taut lines and catenary lines in one system. The line configuration is usually catenary in the static equilibrium position and becomes taut when vessel offsets and the windward lines are stretched.

Working Principle

The magnitude and directionality of the prevailing environment of the wind, waves, and current are the driving parameters of mooring system configuration. They not only dictate the selection of mooring system type, but also the overall system configuration and size.

Under the environmental loading of wind, waves, and current, the floater offset from its mean equilibrium position where mooring forces of all spread mooring lines are balanced in the

horizontal plane. As the floater offset, larger tensions are being generated among the windward lines and tensions on leeward lines reduce (see Fig. 5 for illustration). The imbalance of mooring forces generates a so-called mooring restoring force that counterbalances the environmental forces. The larger the offset, the bigger the mooring restoring force until the acting environment force is balanced by the mooring restoring force. In this way, the offset of the floater is also kept within the design limit (Ma et al. 2019).

In addition to the balance of mean loads, there are also dynamic responses that are generated by the wave and wind actions. The mooring system is designed to accommodate these dynamic responses.

Mooring Components

As the mooring line is typically made up of synthetic fiber rope, wire, and chain or a combination of the three. In some cases, buoyancy modules as well as clump weights can be deployed along the mooring line to achieve specific objectives such as seabed clearance, more desired mooring performance, etc. Environmental factors – wind, waves, and currents – often drive the selection of mooring line materials.

Chain

Chain is extensively used in all mooring systems; especially in shallow waters, the so-called

Spread Mooring System,
Fig. 5 Working principle
of spread mooring system

Spread Mooring System,
Fig. 6 Studlink and
studless chain. (Courtesy of
AsAc)

all-chain design is very popular. It is a simple and effective design taking advantage of the fact that chain is sturdy, has good resistance to seabed abrasion, is heavy to generate the desired catenary shape for compliance to vessel offset and motion, and provides added holding capacity to the anchor. To enhance the station-keeping performance, some of them fit clump weights on ground chain near the touch-down point. The additional weight can increase the restoring force of the mooring system, as the vessel would have to lift those weights before it can offset further.

In terms of chain construction, there are predominantly two types: stud link chain and studless chain (Fig. 6).

Wire

Wire rope is several strands of metal wire twisted into a helix forming a composite “rope,” in a pattern known as “laid rope.” Wire rope for offshore mooring purpose consists of multiple strands, or spiral strand that is round strands as

they have an assembly of layers of wires laid helically over a center with at least one layer of wires being laid in the opposite direction to that of the outer layer.

Because of its lighter weight in comparison to chain, wire rope offers a higher restoring force at the same given pretension because of the less-steep catenary shape of lighter mooring lines. The wire rope also has lower tensile stiffness in comparison to chain which would reduce the dynamic amplification of line tension. It is noted that for the same breaking strength, the wire rope also has cost advantage over the chain (Figs. 7 and 8).

For top and bottom segments of the mooring line, the chain is still preferred for handling and connection to vessel and anchor. Wire rope is widely used as the middle segment in a mooring line, making it a “chain-wire-chain” design. For mobile drilling unit moorings, the line configuration can simply be “wire-chain,” as wire ropes are typically deployed directly from winches on deck where there are no top chains.

Polyester

However, synthetic fiber rope has the lightest weight of all three. For vessels stationed in deep or ultra-deep water, the polyester rope has been increasingly favored over wire rope due to its much lighter weight and lower tensile stiffness. Polyester rope is not only highly competitive in cost, but also offers longer fatigue life than chain and wire rope. “Chain-polyester-chain” design has become a standard makeup for mooring systems in ultra-deep water. Apart from the lower unit weight, polyester also offers lower tensile stiffness which is highly beneficial to mooring

line dynamic tension in harsh environment (Fig. 9).

Anchor

The mooring system relies on the strength of the anchors. The holding capacity of anchors depends on anchor embedment depth and the soil properties. The mooring lines run from the vessel to the anchors on the seafloor. Anchor types include: drag embedment, suction, and vertical load.

A drag embedment anchor (DEA) is the most utilized anchor for moorings. The drag anchor is dragged along the seabed until it reaches the required depth. As it penetrates the seabed, it uses soil resistance to hold the anchor in place. The drag embedment anchor is mainly used for catenary moorings, where the mooring line arrives on the seabed horizontally. It does not perform well under vertical forces.

Suction piles are the predominant mooring and foundation system used for deep water development projects worldwide. Tubular piles are driven into the seabed and a pump sucks out the water from the top of the tubular, which pulls the pile further into the seabed. Suction piles can be used in sand, clay, and mud soils, but not gravel, as water can flow through the ground during installation, making suction difficult. Once the pile is in position, the friction between the pile and the soil holds it in place. It can resist both vertical and horizontal forces.

Spread Mooring System,
Fig. 9 Polyester rope.
 (Courtesy of Lankhost)

Spread Mooring System,
Fig. 10 Various types of
 anchors. (Courtesy of
 Vryhof Anchor)

Vertical load anchors are similar to drag anchors as they are installed in the same way. However, the vertical load anchor can withstand both horizontal and vertical mooring forces. It is used primarily in taut-leg mooring systems, where the mooring line arrives at an angle the seabed (Fig. 10).

Connectors

As the mooring line is usually made of a number of segments with different materials or even the same material, connectors are used to connect the mooring line segments. There are different types

of connectors for different purposes. The commonly used ones include D-shackles for connection the chain segments, D-shackle in association of wire rope termination for connecting the chain to wire rope, and H-link for connecting the chain to polyester segment.

Buoy and Clump Weight

Sometimes, mooring legs are fitted with buoys and clump weights for various design objectives. The buoys can be deployed along the mooring line to lift the line from seabed to avoid say a seabed

pipeline, or near the surface to alter the line catenary shape to achieve improved restoring load characteristics.

Clump weights are typically deployed along the seabed touchdown area to improve the restoring load thus reducing floater offset.

Onboard Mooring Equipment

Mooring line connects to the floater via onboard mooring equipment which includes: fairlead, chainstopper, tensioner, and chain lock. The mooring line typically with chain as top segment goes through the fairlead or chain hawse to terminate at the chainstopper. The chainstopper is a device that allows the chain to be pulled through and locks the chain as soon as pulling in operation stops. Behind the chain stopper, the float is usually fitted with tensioners (typically on the deck) for the winch in or winch out of the mooring line. Chain locker is the chamber for the storage of excess chain.

For some MODUs, the top segment uses wire rope instead of chain. In such a case, the wire rope is pulled through the fairlead directly to onboard winch. The wire is stored on drums which can be rotated to winch in or winch out the wire rope.

Key Applications

Nowadays, the spread mooring system is widely used for offshore station-keeping of drilling and

production platforms, and vessels for designated offshore operations. According to the nature and duration of the offshore operation, the application of the spread mooring system can be divided into the following three categories (Barltrop 1998; API 2018):

1. Mobile mooring system – Suitable for pipe laying vessels, crane vessels, logistics supply vessels, etc. When these vessels are in operation, they need to continuously move the anchors along predetermined route. The movement of the anchors is done by one or two auxiliary ships.
2. Temporary mooring system – Suitable for drilling platforms, drilling ships, drilling operations in certain areas for durations from several weeks to several months.
3. Permanent mooring system – Suitable for a variety of different types of floating structures. Depending on the design life of the oil field, it is necessary to maintain station-keeping in a fixed location for several years to several decades.

The majority of the mobile offshore drilling units and floating production systems use the spread mooring system for station-keeping purpose. For example:

1. A drilling semisubmersible typically uses 8 or 12 mooring lines in four groups connecting the four outward columns to the seabed.

Spread Mooring System,

Fig. 11 Spread mooring system for production semisubmersible. (Courtesy of COTEC)

2. A drillship typically uses four groups of mooring lines connecting the bow and stern of the vessel to the seabed.
3. A production semisubmersible typically uses 8 or 16 mooring lines in four groups connecting the four outward columns to the seabed.
4. A production SPAR typically uses 9 or 12 mooring lines in three groups connecting the outer shell of the platform to the seabed (Figs. 11 and 12).

It is noted that FPSOs typically use single point moorings to allow the vessel to weather vane to minimize the environmental force, but for benign environment or for rounded shape FPSOs, the spread mooring system can be used.

There are other types of offshore systems that also use spread mooring for station-keeping, e.g., CALM offloading buoy, offshore wind turbine, etc. (Figs. 13 and 14).

Static Analysis Method

Gang Ma¹ and Hongwei Wang²

¹Harbin Engineering University, Harbin, Heilongjiang, China

²Harbin Engineering University, Harbin, China

Synonyms

Catenary mooring lines; Taut mooring lines

Definition

Static analysis is a method to find the configuration and tension of mooring line under static equilibrium position. The static load means the forces not changed with time. The mooring line is supposed to be a completely flexible line without bending stiffness in the static analysis (American Petroleum Institute 2005).

Introduction

The catenary theory is usually used to make a static analysis. The classical catenary theory (Faltinsen 1993) and Garrett's rod theory (Garrett 1982) are both under the assumption of nonstretch in the axial direction. The lump-mass method (Korteraayama 1978) also is an effective method which translates the coordinates to assemble the global stiffness matrix. Most of the theories are limited to the assumptions that the axial deformation is small. It is convenient to perform an analysis using the above assumptions, because the chain catenary provides the restoring force due to gravitational effect.

The elastic deformation should be considered for the taut line made of synthetic fibers. The restoring force in the taut line is obtained by axial deformation, and the axial strain is relatively large compared with the chain line. The deformed configuration and reference configuration should be distinguished in the taut line when an analysis is performed. In the following, the elastic catenary theory is introduced.

Elastic Catenary Theory

The catenary method calculates the equilibrium position of the line, with ignoring the effects of bending and torsional stiffness of the line or its end terminations. This method also ignores contact forces between the line and any solid shapes in the model, but it could include all other effects, including weight, buoyancy, axial elasticity, current drag, and seabed touchdown and friction. The catenary position is often quite close to the true equilibrium position, especially when bend stiffness is not a major influence.

It simplifies the static analysis to neglect the effect of elasticity. However, in extreme conditions elasticity should be accounted for. The following demonstrate the elastic catenary theory to include the stretch of the mooring line.

An infinitesimal segment is used to create the equilibrium equations (Fig. 1). The original arc length is ds , and the weight force per length is w . When the cable is stretched, the arc length is described with $d\tilde{s}$, the weight force per length is expressed as $\tilde{w}$. The equilibrium equation is built in horizontal direction, then

$$dH = 0 \quad (1)$$

It means the horizontal force is constant on every point of the line.

Then the equilibrium equations are created in the tangent direction and the normal direction, we get

$$dT = w \sin \varphi ds \quad (2)$$

$$Td\varphi = w \cos \varphi ds \quad (3)$$

When the cable is deformed, the total mass is constant, so

$$wds = \tilde{w}d\tilde{s} \quad (4)$$

The equilibrium equations Eqs. (2), (3), and (4) become to be

$$dT = \tilde{w} \sin \varphi d\tilde{s} \quad (5)$$

Static Analysis Method,**Fig. 1** Infinitesimal segment of the extensible cable

$$Td\varphi = \tilde{w} \cos \varphi d\tilde{s} \quad (6)$$

From Eqs. (5) and (6), the following equation is obtained

$$\frac{dT}{T} = \tan \varphi d\varphi \quad (7)$$

The integration over the segment is performed on Eq. (7), each part of the integration is

$$\int_{T_0}^T \frac{1}{T} dT = \ln T - \ln T_0 \quad (8)$$

$$\int_{\varphi_0}^{\varphi} \tan \varphi d\varphi = -(\ln \cos \varphi - \ln \cos \varphi_0) \quad (9)$$

where T_0 is the tension force on the lower point, φ_0 is the angle between the tangent direction and the horizontal direction on the lower point. From Eqs. (7), (8), and (9), the relationship between the tension and the angle is

$$T = T_0 \frac{\cos \varphi_0}{\cos \varphi} \quad (10)$$

In order to get the horizontal and the vertical distances, the following geometrical relationships are used

$$d\tilde{s}^2 = dx^2 + dy^2 \quad (11)$$

$$dx = \cos \varphi d\tilde{s} \quad (12)$$

$$dy = \sin \varphi d\tilde{s} \quad (13)$$

At the same time, the relationship between the original and the deformed arc length is indicated by the Hooke's law

$$d\tilde{s} = \left(1 + \frac{T}{EA}\right) ds \quad (14)$$

Now the projection of the infinitesimal arc length in the horizontal direction is obtained by Eqs. (12) and (14)

$$dx = \cos \varphi \left(1 + \frac{T}{EA}\right) ds \quad (15)$$

Subtracting Eq. (3) from Eq. (15), we get

$$dx = \cos \varphi \left(1 + \frac{T}{EA}\right) \frac{T}{w \cos \varphi} d\varphi \quad (16)$$

With the help of Eq. (10), Eq. (16) becomes

$$\begin{aligned} dx &= \cos \varphi \left(1 + T_0 \frac{\cos \varphi_0}{\cos \varphi} \frac{1}{EA}\right) T_0 \frac{\cos \varphi_0}{\cos \varphi} \frac{1}{w \cos \varphi} d\varphi \\ &= \left(\frac{T_0 \cos \varphi_0}{\cos \varphi} \frac{1}{w} + \left(\frac{T_0 \cos \varphi_0}{\cos \varphi} \right)^2 \frac{1}{EA w} \right) d\varphi \\ &= \left(\frac{H_0}{w \cos \varphi} + \frac{H_0^2}{w EA \cos^2 \varphi} \right) d\varphi \end{aligned} \quad (17)$$

For the project of the infinitesimal arc length in the vertical direction, the same process is

performed with the help of Eqs. (3), (10), (13), and (14), we get

$$\begin{aligned}
 dy &= \sin \varphi d\tilde{s} \\
 &= \sin \varphi \left(1 + \frac{T}{EA} \right) ds \\
 &= \sin \varphi \left(1 + \frac{T}{EA} \right) \frac{T}{w \cos \varphi} d\varphi \\
 &= \sin \varphi \left(1 + T_0 \frac{\cos \varphi_0}{\cos \varphi} \frac{1}{EA} \right) T_0 \frac{\cos \varphi_0}{\cos \varphi} \frac{1}{w \cos \varphi} d\varphi \\
 &= \left(\frac{T_0 \cos \varphi_0 \sin \varphi}{w \cos^2 \varphi} + \sin \varphi \frac{(T_0 \cos \varphi_0)^2}{\cos^3 \varphi} \frac{1}{wEA} \right) d\varphi \\
 &= \left(\frac{H_0 \sin \varphi}{w \cos^2 \varphi} + \frac{H_0^2 \tan \varphi}{wEA \cos^2 \varphi} \right) d\varphi
 \end{aligned} \quad (18)$$

The horizontal distance is calculated with the integration over the cable on Eq. (17)

$$\int_{x_0}^x dx = \int_{\varphi_0}^{\varphi} \left(\frac{H_0}{w \cos \varphi} + \frac{H_0^2}{wEA \cos^2 \varphi} \right) d\varphi \quad (19)$$

$$\begin{aligned}
 x - x_0 &= \frac{H}{w} \left[\ln \left(\frac{1}{\cos \varphi} + \tan \varphi \right) \right. \\
 &\quad \left. - \ln \left(\frac{1}{\cos \varphi_0} + \tan \varphi_0 \right) \right] \\
 &\quad + \frac{H^2}{wEA} (\tan \varphi - \tan \varphi_0)
 \end{aligned} \quad (20)$$

Here the following equations are used in order to get a simplified formulation. Define

$$z = \ln \left(\frac{1}{\cos \varphi} + \tan \varphi \right) \quad (21)$$

then the following equation can be got easily

$$\begin{aligned}
 \sinh z &= \frac{e^y - e^{-y}}{2} \\
 &= \frac{\left(\frac{1}{\cos \varphi} + \tan \varphi \right) - \left(\frac{1}{\cos \varphi} - \tan \varphi \right)}{2} \\
 &= \tan \varphi
 \end{aligned} \quad (22)$$

Meanwhile, the relationship between the angle and the tension in the catenary line is

$$\tan \varphi = \frac{V}{H} \quad (23)$$

where V is the vertical force, H is the horizontal force.

From Eqs. (22), (23), we get

$$\sinh z = \frac{V}{H} \quad (24)$$

With the help of Eq. (1) and Eq. (24), Eq. (20) becomes

$$\begin{aligned}
 x - x_0 &= \frac{H}{w} \left[\operatorname{arsh} \frac{V}{H} - \operatorname{arsh} \frac{V_0}{H} \right] \\
 &\quad + \frac{H(V - V_0)}{wEA}
 \end{aligned} \quad (25)$$

The vertical distance is also calculated with the same process

$$\int_{y_0}^y dy = \int_{\varphi_0}^{\varphi} \left(\frac{H_0 \sin \varphi}{w \cos^2 \varphi} + \frac{H_0^2 \tan \varphi}{wEA \cos^2 \varphi} \right) d\varphi \quad (26)$$

$$\begin{aligned}
 y - y_0 &= \frac{H}{w} \left(\frac{1}{\cos \varphi} - \frac{1}{\cos \varphi_0} \right) + \frac{H^2}{2wEA} (\tan \varphi - \tan \varphi_0) \\
 &= \frac{H}{w} \left(\sqrt{1 + \left(\frac{V}{H} \right)^2} - \sqrt{1 + \left(\frac{V_0}{H} \right)^2} \right) + \frac{V^2 - V_0^2}{2wEA}
 \end{aligned} \quad (27)$$

Put the coordinate system on the lower point of the catenary line. If there is no vertical force on the lower end of the catenary line, the boundary conditions on the lower point are $x_0 = 0$, $y_0 = 0$, $\varphi_0 = 0$, $V_0 = 0$, the boundary conditions on the upper point is $V = wL$, Eq. (25) and Eq. (27) become to be

$$x = \frac{H}{w} \left(\operatorname{arsh} \frac{wL}{H} \right) + \frac{HL}{EA} \quad (28)$$

$$y = \frac{H}{w} \left(\sqrt{1 + \left(\frac{wL}{H} \right)^2} - 1 \right) + \frac{wL^2}{2EA} \quad (29)$$

So the dimensionless form of the extensible catenary theory is

$$\frac{x}{L} = \frac{H}{wL} \left(\operatorname{arsh} \frac{wL}{H} \right) + \frac{H}{EA} \quad (30)$$

$$\frac{y}{L} = \sqrt{1 + \left(\frac{H}{wL} \right)^2} - \frac{H}{wL} + \frac{wL}{2EA} \quad (31)$$

The catenary algorithm is robust and efficient for most realistic cases but it cannot handle cases where the mooring line is in compression. Since the bending stiffness and other effects are ignored in this method, thus, the compression means the mooring line is slack and no unique solution. The catenary method is iterative and may fail to converge. It may be possible to solve this by adjusting the catenary convergence parameters.

Definition

The station-keeping system for very large floating structures (VLFS) is a group of interacting or interrelated entities that maintain VLFS in the desired position or keep these relatively static with respect to other floating structures in the presence of wind, waves, and currents. The station-keeping system for VLFS is commonly classified into two categories, namely the mooring system and the dynamic positioning (DP) system. The appropriate type of station-keeping system needs to be selected to create a balance among functionality, cost, and requirements of the VLFS, and this may be

achieved through selection, survey, research, design, verification, and development. The ultimate objective of the station-keeping system for VLFS is to improve the stability and safety of the structures, and fulfill functionality requirements and provide long-term services.

Fundamental Scientific Principles

As a permanent or semipermanent engineering project, VLFS have major characteristics that differ from typical offshore structures, such as long service life, reasonable maintenance expenses, and favorable fatigue resistance (Lamas-Pardo et al. 2015). Mooring and DP systems are two main methods used to keep VLFS in position under the effects of wind, waves, and currents.

Globally, VLFS are currently at the design stage, except for the Mega-Float in Tokyo Bay, the only manufactured VLFS in existence. Although VLFS projects are incomplete, these have inspired research on VLFS behavioral problems and station-keeping system design.

Mooring System for VLFS

The mooring system is a widely used station-keeping technique for floating structures in moderate water depth, as used in VLFS projects such as Mega-Float in Japan (Shimada and Miyajima 2002; Sato and Inoue 2003). Mooring types for VLFS normally include mooring lines (e.g., cables and tension legs), rubber fender-dolphin, and pier wall (Fig. 1).

A mooring system, comprising several types of lines [e.g., catenary mooring line, taut mooring line, and tension leg mooring line (Journée and Massie 2001)], is a common station-keeping technique used for VLFS, in which restoring forces are

provided by the weight or elasticity of the mooring line. The mooring system for VLFS is functionally similar to that used for conventional offshore structures and has large-scale, special functionality owing to unique inherent features including (a) the high number and strong tension forces of mooring lines (few mooring lines cannot maintain station-keeping, and this leads to design difficulty and rising costs); (b) for modular VLFS, the mooring system should work with connectors mainly utilized to keep relative motions of adjacent modules as small as possible; (c) the elastic deformation of VLFS gives rise to large perturbations of certain mooring lines; and (d) asymmetrical mooring systems need to be adopted when VLFS are deployed near islands and reefs, where incident wave and bathymetry may be nonhomogeneous owing to the large scale of VLFS.

The description above implies that the design of mooring systems for VLFS is challenging due to the large dimension, complex characteristics of the sea surface, and uneven seabed conditions. Specific issues relating to the design of mooring systems for VLFS include the following:

- Nonuniform distribution of incident waves acting on different modules of VLFS leads to rugged motion responses along the VLFS, increasing variability in mooring line tensions.
- The effect of the elastic deformation may become obvious as the dimension of VLFS increases, resulting in a coupled response on mooring line tension.
- The complex seabed profile and significantly varying water depth always exist owing to the large dimension of VLFS; asymmetry mooring schemes attached with logically distributed buoys and clump weights may be utilized to achieve adequate mooring line shapes.

Station-Keeping System for VLFS, Fig. 1 Various types of mooring systems for VLFS: (a) cable/chain, (b) tension leg, and (c) rubber fender-dolphin (Wang and Tay 2011)

DP System for VLFS

In deep ocean situations, where VLFS such as mobile offshore bases (MOB) serve as floating airports, designing suitable mooring systems is challenging since the runway must be consistently aligned into the wind for planes to land with maximum control, and the cost of mooring lines increases substantially with the increasing water depth (Girard et al. 2003a). In such situations, the DP system is employed for station-keeping as this system has the advantages of rapid maneuvering and evacuation, favorable adaptation to environmental conditions, and sound station-keeping abilities regardless of water depth and seabed conditions (Fig. 2).

DP system development for VLFS is based on that for typical offshore structures and consists of four subsystems, namely the power system, thruster system, control system, and position reference system but with more stringent safety requirements. Inspired by emerging floating nuclear power plant concepts, the power system of DPS for VLFS can emulate this technology to supply sustainable power to the thrust system and other facilities. The thruster system is subjected to strict safety checks and fatigue analysis prior to installation to ensure sufficient thrust throughout the operational life of the VLFS. The control system must include manual autoposition modes that are integrated with assembly and emergency disassembly modes for MOB comprising multiple modules (Girard and Hedrick 2000). Essentially, the upper-level control law should be strictly examined with high robustness, fault tolerance, and risk avoidance, while the low-level control

law needs to distribute the commanded thrust force to all available thrusters of the VLFS in a manner that ensures optimization of energy, reduction of thrust force error, and adaptation to thruster failure/saturation. The position reference system is the “eye” of the DP system and needs to establish a credible system using Global Positioning Systems (GPS), underwater acoustic positioning systems, and laser positioning systems. An emergency situation in which all the positioning reference systems fail needs to be adequately addressed.

To avoid intensive hydroelastic loads of the VLFS, MOB dedicated to operating in the open sea commonly adopt modular design. Each module needs to be able to perform long-term station-keeping at sea. The modules can be assembled and maintain an absolute position in the global coordinate system and relative position to adjacent modules. Specific issues relating to DPS design for VLFS include the following:

- The DPS needs to maintain the overall position and orientation of all modules to be aligned with dominant wind, waves, and local currents in the predetermined operational site.
- Relative positions between modules should be properly constrained to avoid collisions and disjunctions, and suppress connector loads in a tolerant range to accomplish VLFS functionality.
- In emergency conditions, modules can be quickly disassembled and kept in the safe distance between each other to guarantee the safety of staff and equipment on the module. In harsher environments, modules can transfer to the nearest safe zones in an efficient and organized manner.
- The DPS can efficiently mobilize modules into the operational configuration.

Station-Keeping System for VLFS, Fig. 2 Scaled MOB module equipped with a dynamic positioning system (Girard et al. 2003a)

Key Applications

VLFS can be classified into two types based on geometry, i.e., the pontoon type and the semisubmersible type. Three projects, namely Mega-Float, MOB, and multimodule VLFS, are

presented to describe the applications of different station-keeping systems.

Station-Keeping System for Mega-Float

Mega-Float is a large pontoon-type VLFS designed for a floating airport deployed in protected waters (Isobe 1999). Figure 3 shows the design concept of Mega-Float utilizing the rubber fender-dolphin mooring system to restrain horizontal motions of the float. The fenders are attached to Mega-Float to have 0.1 m clearances between fenders and dolphins in the zero-load condition. Several studies have investigated the mooring feasibility of Mega-Float in various conditions such as slowly varying drift motion in irregular waves (Namba et al. 2000) and nonlinear mooring forces in the time domain (Shimada and Miyajima 2002). The sea environment in Tokyo Bay is relatively mild, and water is shallow. Kato et al. (2002) performed a quantitative risk analysis of multiple mooring dolphins for Mega-Float and found that the mooring design method was nearly appropriate if the yield strength of the dolphins was at least 2.5 times the design load.

Shimada and Miyajima (2002) conducted a sea scale model experiment of Mega-Float with a six-fender-dolphin mooring system. Restoring loads provided by deformation of the fender were measured and horizontal motion responses of Mega-Float analyzed during the sea tests. The rubber fender-dolphins could effectively restrain the motions of Mega-Float and had the lowest construction and maintenance costs.

Station-Keeping System for MOB

In a deep ocean environment, Mega-Float may not be the best choice in terms of hydrodynamic

properties and costs of mooring systems. MOB may be more suitable due to the superior performances in waves (Palo 2005). MOB consists of several modules that are maneuvered into position and joined to form a single base. The US Navy supported a substantial research effort throughout the twentieth century to develop a suitable design for this concept. Mooring lines are not considered suitable for MOB, since the runway must be consistently aligned into the wind for planes to land with maximum control. At the beginning of the twenty-first century, a team from the University of California Berkeley developed an automated multimodule dynamic positioning (MMDP) control system for MOB and a simulation template for uniform support of DP control systems during tests and evaluations (Girard et al. 2003a). Rapidly forming or breaking connections between MOB components and reorientation of the entire MOB string in the direction of the wind can be achieved with the help of the control system (Girard and Hedrick 2000). Figure 4 illustrates the concept of the connected multimodule

Station-Keeping System for VLFS, Fig. 4 Simulation with three MOB modules in Berkeley's tank test (Girard et al. 2003b)

Station-Keeping System for VLFS, Fig. 3 Mega-Float with rubber fender-dolphin mooring system (Fujikubo and Suzuki 2015)

DP-derived MOB. During a 4-year program, several technical contributions were made to the MMDP: A complete system including the control, power, and thruster system was designed and developed based on a conventional PID controller; a corresponding model test was conducted to investigate and validate the control strategy of the MMDP; and a fundamental study was conducted to examine the mathematical model and real-time numerical simulations. The MOB program ended in 2000 since this was considered a less cost-effective solution than existing solutions such as a combination of aircraft carriers and support vessels for addressing logistical issues (Lamas-Pardo et al. 2015).

Station-Keeping System for Multimodule VLFS

In recent years, institutes and universities in China invested a great deal of effort in investigating the feasibility of multimodule VLFS near islands and reefs. Unlike MOB, mooring systems are employed with a comprehensive consideration of cost and safety requirements. Studies in China mainly focus on four aspects, i.e., hydroelasticity (Wu et al. 1993), effects of complex geographic environments on mooring systems (Cui et al. 2001), influences of nonuniform incident waves (Ding et al. 2017), and various types of mooring systems (Wang et al. 2017).

Based on the hydroelastic theory proposed by Wu (1984), a numerical method was established by Fu et al. (2007) to consider the coupled effects of the mooring system and hydroelasticity, and this was validated by experiments. Wu et al. (2017) and Ni et al. (2018) subsequently compared the mooring tensions between the flexible and rigid models of the module numerically and found that effects of the elastic deformation of the VLFS on the mooring tension can be significant in severe water conditions. A wave basin model test (Fig. 5) revealed that nonuniform distribution of the incident waves acting on different modules of VLFS leads to rugged motion configurations along the VLFS, increasing variety of the mooring line tensions (Wei et al. 2018; Ding et al. 2019). Apart from the coupled effects of hydroelasticity and mooring, various types of mooring systems have been investigated, including catenary mooring systems, taut mooring systems, and catenary-taut-tendon hybrid mooring systems (Wang et al. 2017, 2018). An optimization method for designing mooring systems for VLFS was proposed based on Genetic Algorithm and a vessel-mooring coupled model (Liang et al. 2019). Experimental evaluation of a mooring system simplification methodology for reducing mooring lines in a VLFS model testing was carried out (Liang et al. 2020). Results from a recent at-sea experiment of a two-module small-scale VLFS may be forthcoming.

Station-Keeping System for VLFS, Fig. 5 A wave basin test considering nonuniform incident waves, nonuniform seabed, multimodule coupling, and mooring system (Wu et al. 2018)

Future Challenges

In this entry, a summary of research and applications of station-keeping systems for VLFS emphasizing specific considerations that are far more complicated than those for conventional offshore structures is presented. Although significant progress has been made in the study of station-keeping systems for VLFS, to meet the challenge of analyzing and predicting complex ocean environment-induced motion responses, a great deal of work needs to be undertaken, particularly in the following areas:

1. The large dimension of VLFS alters the mooring system design input for traditional oil platforms, including nonuniform sea environment conditions and seabed conditions along the lengthy direction of the VLFS, elastic deformation of the VLFS, very large connector loads induced by asynchronous motion responses of adjacent modules, and mooring line deployment and dynamic response caused by seabed effects. Anchor-soil interactions can greatly challenge numerical modeling, prediction and experimental validation of the station-keeping ability of VLFS, and the mooring system design from an engineering perspective.
2. As a permanent station-keeping system for VLFS, mooring line tension, mooring chain ductile failure, and anchor-soil interactions need to be monitored in real time. Comprehensive methods combining statistic tools, probability theory, machine learning, and big data technology need to be developed to analyze monitoring results, predict operational risk over a short period of time and remaining lifetime of the mooring chain over a long period of time, and undertake temporary and permanent procedures to guarantee operational safety of the mooring system.
3. MOBs are likely to encounter more severe and complex environmental loads in the deep sea than VLFS near islands and reefs. High-level controller methods dedicated to tackling fast docking, emergency evacuation, and independent standby positioning should be developed in cases of thruster failure, DGPS signal failure, and connector failure. Local position reference systems with high reliability need to be developed to back up the global position reference system.
4. MOBs intended to serve in the deep sea are usually the semisubmersible form that can reduce wave loads. However, the relatively small water-plane area inherently leads to discernible coupling characteristics in the dynamics and kinematics between the horizontal and vertical planes. A positioning controller integrated with roll and pitch motion suppression needs to be developed to maintain the relative position and attitude of the modules, reducing the connector loads in all degrees of freedom (DoFs) and fulfilling the functionality of the VLFS.
5. The station-keeping system for VLFS needs to be easily operable, have abundant functionality, high robustness, and favorable compatibility, and be capable of integrating with artificial intelligence, green power, carbon dioxide emission reduction and have an environment-friendly interface to the ocean space and seabed.

Steel Catenary Risers

► Pipeline Soil Interactions

Steel Pipelines and Risers

Xinglan Bai
School of Naval Architecture and Maritime,
Zhejiang Ocean University, Zhoushan,
The People's Republic of China

Synonyms

Blowout preventer (BOP); External tieback connector (ETBC); Floating production storage and transportation systems (FPSO); Internal tieback connector (ITBC); Material takeoff (MTO); Tension leg platforms (TLP); Top tensioned risers (TTRs); Vortex-induced motions (VIMs); Vortex-induced vibrations (VIV)

Definition

Pipelines and risers are used for a number of purposes in the development of offshore hydrocarbon resources. These include the export (transportation) pipelines, flow lines to transfer product from a platform to export lines, water injection or chemical injection flow lines, Flow lines to transfer product between platforms, subsea manifolds and satellite wells, and pipeline bundles.

Design Stages

Submarine pipelines, steel catenary risers, and top tensioned risers are included in the book. The design of pipelines and risers is usually performed in three stages, namely:

1. Conceptual engineering

Conceptual engineering is normally:

- To establish technical feasibility and constraints on the system design and construction
- To eliminate nonviable options
- To identify the required information for the forthcoming design and construction
- To allow basic cost and scheduling exercises to be performed
- To identify interfaces with other systems planned or currently in existence

2. Preliminary engineering

The system concept is fixed for the primary design of the pipeline. This will include:

- To verify the sizing of the pipeline
- Determining the pipeline grade and wall thickness
- Verifying the pipeline against design and code requirements for installation, commissioning, and operation

3. Detail engineering

The detailed engineering phase is, as the description suggests, the development of the design to a point where the technical input for all procurement and construction tendering can be defined in sufficient detail.

The primary objectives can be summarized as follows:

- Route optimization
- Selection of wall thickness and coating

- Confirming code requirements on strength, vortex-induced vibrations (VIV), on-bottom stability, global buckling, and installation
- Confirming the design and/or performing additional design as defined in the preliminary engineering
- Development of the design and drawings in sufficient detail for the subsea scope. This may include pipelines, tie-ins, crossings, span corrections, risers, shore approaches, and subsea structures
- Preparing detailed alignment sheets based on most recent survey data
- Preparation of specifications, typically covering materials, cost applications, construction activities (i.e., pipelay, survey, welding, riser installations, spool piece installation, subsea tie-ins, subsea structure installation), and commissioning (i.e., flooding, pigging, hydrotest, cleaning, drying)
- Preparing material takeoff (MTO) and compiling necessary requisition information for the procurement of materials
- Preparing design data and other information required for the certification authorities

Design Process

The object of the design process for a pipeline is to determine, based on given operating parameters, the optimum pipeline size parameters.

Submarine Pipeline

Submarine pipelines have become important offshore oil and gas field production facilities and are the “artery” of offshore oil and gas production systems. Since the first submarine pipeline was laid in 1954, the length of submarine pipelines laid in the world has exceeded more than 100,000 km. Submarine pipelines are used for transporting three main substances: gas, oil, and water. Submarine gas and oil pipelines fall into three groups: intra-field pipelines, which are used to bring the oil or gas from wellheads to a point within the operating field for collection, processing, and onward transport; export

pipelines, which transport the gas and oil to land; and transport pipelines, which have no necessary connection with the operating field but transport gas or oil between two places on land. The last category is often included with the export pipelines.

Process Design

Submarine pipeline process design: Determine the submarine pipeline transportation process scheme according to the basic data including oil and gas field development scale, physical properties of oil and gas, natural conditions, as well as the overall development layout; through simulation and calculation in different operating modes, determine the best design and running data and ensure economic and reasonable running of pipelines.

Structure Design

Submarine oil and gas pipeline structure design technology: Calculate and analyze a submarine pipeline according to the route information on the submarine pipeline and the environmental conditions of the sea area including wind, wave and current, soil and geology conditions, internal fluid, platform displacement data, etc., thus ensuring that the submarine pipeline runs safely in its whole life cycle. Conventional calculation and analysis generally involve pipeline stability, on-bottom strength, riser strength, crossing, installation, etc.

Anticorrosion Design

The anticorrosion design technology for submarine pipelines is the key technology for ensuring long period safe operation of submarine pipelines in severe corrosive environment. For long-distance oil and gas pipelines or water transportation pipelines with various pipe diameters and operating conditions, select a correct and effective internal and external anticorrosion scheme; determine reasonable pipeline materials, coating systems, patching materials, and corrosion inhibitors; and take some measures like corrosion monitoring device design and other ways to ensure long-term effective and stable running of pipelines.

Construction and Installation Technology with Pipe Laying Ship Method

The construction and installation technology with pipe laying ship method includes process design technology for pipe laying operation line, pipeline behavior mechanics analysis technology, and mooring analysis technology. Simulate a submarine pipeline into a series of continuous beam elements using international standards and specifications and the elastic finite element method; simulate the tightener, support roller, and submarine boundary condition into rigid or elastic supports. The pipeline forms an S curve between the pipe laying ship and the mud landing point, and the curve is divided into upper bending section and lower bending section.

Construction with Drag Method

The construction technology with drag method: Bind a flotation buoy on a pipeline and make it float in water; then drag the pipeline to the pipeline design route using the tools such as ship and others; finally place the pipeline to the seabed. According to the state of the pipeline during towing in water, the drag method is divided into bottom drag method, off-bottom drag method, floating drag method, etc.

Submarine Pipeline Construction Complete Technology

The submarine pipeline construction complete technology includes horizontal interface docking technology, riser expansion bend installation technology, elastic laying technology, etc.

Submarine transport pipelines are used mainly for the transport of gas and are located predominantly around the Mediterranean and the Baltic and North Seas. Many have been created since 2000. In the Mediterranean, the earliest gas pipeline was the Trans-Mediterranean Pipeline, built in 1983 to link Algeria and the Italian mainland, via Sicily. This was followed in 1996 by the Maghreb-Europe Pipeline to link Morocco and Spain across the Strait of Gibraltar. Subsequent Mediterranean pipelines are the Greenstream Pipeline, built in 2004 between Libya and Sicily; the interconnector built in 2007 between Greece and Turkey; the link completed in 2008 between

Arish in Egypt and Ashkelon in Israel (which has been out of service since 2012); and the Medgaz Pipeline built in 2011 between Algeria and Spain. Further north, a link was built between Scotland and Northern Ireland in the United Kingdom in 1996. An interconnector was built between Belgium and the United Kingdom in 1998. The Balgzand/Bacton Line (BBL) connected the Netherlands and the United Kingdom in 2006. Finally, the Nord Stream Pipeline was completed in 2011 and 2012 through the Baltic, between Vyborg in the Russian Federation and Kiel in Germany. This is the longest gas transport pipeline in the world (1,222 km in length). Issues about its environmental impact bulked large in the negotiations leading to its construction, and particular problems were encountered over munitions dumped in the Baltic at the end of the Second World War (see Chap. 24 (Solid Waste Disposal)).

0.2 There are also a number of gas pipelines linking Norwegian gas production to its export markets. The Norwegian upstream gas transportation system has been developed from the 1970s and continues to develop, to cater for the transportation of natural gas produced on the Norwegian continental shelf. Norwegian domestic consumption of natural gas is limited. Almost all the gas produced is exported (101,000 million standard cubic meters) to European gas markets through landing terminals in Belgium, France, Germany, and the United Kingdom. The pipeline network in 2014 forms a 7,980-km integrated transportation system, transporting gas from nearly 60 offshore fields and 3 large gas processing plants on the Norwegian mainland, to European gas markets. The latest main addition to the system is the Langeled Pipeline, opened in 2007, which goes from the onshore processing plant in Norway for the Ormen Lange gas field to the United Kingdom, via a riser platform at the Sleipner field.

Outside Western Europe and the Mediterranean, there is a gas pipeline linking the Russian Federation and Turkey across the southeastern corner of the Black Sea and one linking the island of Sakhalin to the mainland of the Russian Federation in the North-West Pacific. Oil transport pipelines exist between Indonesia and Singapore

across the Strait of Malacca and, in China, linking the island of Hainan to Hong Kong. Generally, these submarine transport pipelines have been built and financed by oil and gas operators (including national oil and gas companies), sometimes in consortiums with national gas distribution undertakings.

Steel Riser

General

A riser system is essentially conductor pipe connection floaters on the surface and the wellheads at the seabed. There are essentially two kinds of risers, namely, rigid risers and flexible risers. A hybrid riser is the combination of these two.

The riser system of a production unit is to perform multiple functions, both in the drilling and production phases. The functions performed by a riser system include:

- Production/injection
- Export/import or circulate fluids
- Drilling
- Completion and workover

A typical riser system is mainly composed of:

- Conduit (riser body)
- Interface with floater and wellhead
- Components
- Auxiliary

The riser system must be arranged so that the external loading is kept within acceptable limits with regard to:

- Stress and sectional forces
- VIV and suppression
- Wave fatigue
- Interference

The riser should be as short as possible in order to reduce material and installation costs, but it must have sufficient flexibility to allow for large excursions of the floater.

Catenary and Top Tensioned Risers

In shallow water, it has been practiced to use top tensioned risers (TTRs), but as design for larger water depth, it has been accounted that the need for new design practice has increased. The ordinary TTR is very sensitive to the heave movements due to wave and current loads because the rotation at the top and bottom connections is limited. The heave movement also requires top tensioned equipment to compensate for the lack of tension. If the top tension is reduced, it will cause large bending moment along the riser especially if the riser is located in environment with strong current. If the effective tension becomes negative (i.e., compression), then Euler buckling will occur.

The catenary riser is self-compensated for the heave movement, i.e., the riser is lifted or lowered on the seabed. The catenary riser still needs a ball joint to allow for rotation induced by waves, current, and vessel motion, at the upper end connection.

The catenary riser is sensitive to environmental loads, i.e., wave and current, due to the normally low effective tension in the riser. The fatigue damage induced by vortex-induced vibration (VIV) can be fatal to the riser. Use of the VIV suppression devices such as helical strakes and fairing can reduce the vibration by 70–90%.

Steel Catenary Riser (SCR)

In recent years, oil and gas development and exploration activities in deep-water development have become more and more frequent, and the water depth has reached deep-water and even ultra-deep-water compared to previous years. With the increasing application of water depths, the technical equipment for deep-water development has also been facing new challenges, and the key technical equipment involved mainly includes the upper offshore platforms, and riser systems have also been developed in this challenge time and time again. From the beginnings of compliant platforms, tension leg platforms (TLP), single column platforms (Spar) and semi-submersible platforms to today's floating production systems and floating production storage and transportation systems (FPSO), the offshore platforms are better suited to the harsh marine environment. Among the currently

available riser systems, flexible risers, although they can comply with the drifting and lifting and sinking movements of floating bodies, are more costly and have some technical problems that have not been solved and are not adapted to the high temperature and pressure environment of offshore oil and gas extraction. This is when the steel suspended flow line riser was considered the most effective solution to emerge. It emerged in the mid-1990s and has been developed by many researchers and scholars and is now being used in the Gulf of Mexico, the North Sea, Camps Bay, and West Africa. This entry focuses on the basics of steel suspended flow line risers and the prospects for their application.

Structural Features and Advantages of SCR

SCR is called steel catenary riser, which is a combination of subsea pipeline and riser, where one end is connected to the upper floating platform and the other end is connected to the lower wellhead, without the connection of subsea stress joints, which greatly reduces the construction difficulty of the overall structure. There are some advantages of SCR, such as low cost, no upper top tension compensation, high tolerance to float drift and lifting and sinking movements, and suitability for high temperature and pressure environments. These features have led to the replacement of flexible and top tensioned risers as the riser system of choice for deep-water oil and gas resources development. Since 1994, when Shell laid the world's first steel catenary riser in the Gulf of Mexico at a water depth of 872 m, SCR has attracted widespread attention from the engineering and academic communities and is gradually gaining favors in the field of deep-water development.

Since the introduction of the steel catenary riser in the Gulf of Mexico, various new types of steel catenary risers have been introduced and developed to meet the needs of different water depths, and several different forms of steel catenary risers have emerged – simple catenary risers, steep wave risers, lazy-wave catenary risers, shaped steel catenary risers, mini-lazy-wave risers, and bottom weighted risers – and can be seen from Fig. 3. The simple catenary riser has a limited length of catenary available

for hull movement and is therefore mainly suitable for platforms with small hull movements; the other risers have greater compliance with hull translational movements than the simple catenary riser and can be more easily adapted to slow drifting movements with large floating hull structures (Fig. 2) and FPSOs (Fig. 1). The lazy-wave catenary riser and steep-wave catenary risers are raised by the addition of buoyancy sections.

The unique structural form of the steel catenary riser also poses new challenges for its design, manufacture, installation, and safe service. Among the factors controlling the design and safe service of the riser are the fatigue life of the top joints and touchdown points and the interaction between the flow line section and the seabed. Current research has shown that when a floating body moves in response to wind, waves, and currents, the overhanging section and the flow line section move simultaneously with the floating

body, causing the touchdown points to change along the axis and causing the flow line section to interact with the seabed. The fatigue damage at the touchdown point is mainly caused by the floating body movement and vortex-induced vibration, the stiffness of the seabed has a greater impact on the fatigue damage at the touchdown point, and the greater the seabed stiffness, the more serious the fatigue damage caused by the interaction between the riser and the seabed. Fatigue damage at the top is mainly caused by waves.

The Main Steps of SCR Design

The main design steps for the SCR include:

1. **Determine the required dimensions of the riser.**

The dimensions of the riser need to be determined mainly include wall thickness, inner and outer riser diameter, riser length, top suspension angle, etc.

Steel Pipelines and Risers, Fig. 1 SCR with FPSO

Steel Pipelines and Risers, Fig. 2 SCR with different platform

Steel Pipelines and Risers, Fig. 3 Configurations of SCR

2. Static load design.

Static load design is mainly used to ensure that the stress in the critical area is within the allowable stress range when loaded with the load specified in the code; the main codes used here are API RP 2RD.

3. Dynamic load design.

The SCR motion response has natural non-linear characteristics, and it is easier to capture

the ultimate response values associated with wave forces and hull motion using time domain simulations than using frequency domain simulations.

4. Vortex-induced vibration computational analysis.

This section determines the sizing of vortex-induced vibration suppression devices.

5. **Fatigue analysis.**

Fatigue damage includes fatigue damage caused by vortex-induced vibration and fatigue damage caused by soil-riser interaction. The calculation of fatigue damage is determined based on the S-N curve specified in the code, partly applied to the code such as API RP 2A (1993).

6. **Flexible joint correlation analysis.**

This part mainly analyzes the ultimate stress at the upper point.

7. **Installation load analysis.**

This is used to analyze the installation load checks that occur when the joint is installed only at sea.

Analysis Methods for SCR

There are three main types of SCR analysis: numerical simulations, model tests, and field test monitoring analysis.

1. **Numerical simulation**

It is very difficult to use purely theoretical methods to analyse the riser with complex conditions, which include the direction of the catenary not only interact with the seawater,

but also in the area of the touchdown point will also interact with the seabed soil.

2. **Model tests**

Model tests are generally divided into scaled-down model tests and full-scale model tests (Fig. 4). In the scaled-down model, the riser and pipe diameter data are significantly different from the actual model, which can reveal the dynamic response of the actual riser in some respects. The full-scale model test can simulate the real dynamic response of the riser more accurately; the full-scale simulations of the STRIDE JIP and CARISIMA JIP have provided much valuable information for the study of the mechanism of SCR riser-soil interactions; Fig. 5 shows the experimentally obtained curve of the effect of the riser pullout speed on the suction force. Lots of related tests have been carried out on this basis, but it is more costly than the scaled-down model. There is still some discrepancy and simplification between the conditions considered and the actual sea conditions, so a more suitable test model should be selected when choosing the model test, considering all circumstances.

Steel Pipelines and Risers, Fig. 4 Full-scale model test

Steel Pipelines and Risers, Fig. 5 CARISMA JIP model of uplift resistance

3. Field test monitoring and analysis

The field test monitoring analysis is based on the existing installation of the riser, some monitoring instruments are installed in the field riser to measure the dynamic response data of the riser, and based on these data, the analysis can provide reference significance for the subsequent numerical simulation.

Key Technologies for SCR

The key technologies of SCR are mainly focused on the following aspects:

1. The effect of floating body motion

SCR is mainly used to connect floating platforms to subsea wellheads, and floating structures generate large motion responses under the action of wind and wave currents. These responses mainly include first-order high-frequency responses and second-order low-frequency responses. The first-order motion of the floating body is an oscillation in the equilibrium position, which has a small amplitude and high frequency, causing a low-stress fatigue cycle in the riser, which forms the bulk of the high perimeter fatigue damage at the top of the riser. The second-order slow drift motion of the floating body consists of two main components, one being the large drift caused by wind and current and the other

being the small amplitude oscillations caused by waves. In addition, the motion of the floating body can have an important effect on the motion of the riser touchdown points.

2. Interaction with the seabed soil

As the SCR moves with the floating body, its flow line segments interact with the seabed and are the most important parameter affecting the fatigue cycle at the touchdown point. Under the repeated action of the riser, trenches will be formed in the seabed, the width of which is generally 2 to 3 times the diameter of the riser and the depth of which is generally 0.5 to 1 times the diameter of the riser. The formation of the trench has a greater impact on the movement of the riser. When a substantial drift of the floating body occurred under the storm, the pull-out motion of the flowline and out of the plane movement will be subject to the resistance of the trench, causing the riser local stress increases. The riser tension is large when the suspension catenary is in a taut state, and the impact of the trench is particularly serious. Seabed stiffness model can be divided in two major categories just as shown in Figs. 6 and 7.

3. Vortex-induced vibration (VIV)

The fatigue damage caused by vortex-induced vibration is mainly concentrated in the static touchdown point; the nature of the

Steel Pipelines and Risers, Fig. 6 The RQ pipe-soil model

damage is high stress cycle of low circumference fatigue damage. The main influencing factors include the lifting and sinking motion of the floating body and the pulsating component of the second-order response, the subsea stiffness, and the dynamic characteristics of the eddy forces. VIV in steel catenary risers can be effectively controlled by welding spiral reinforcement plates to the first half of the catenary section. Studies have shown that a moderate rib height can effectively control the separation of the boundary layer and prevent alternating vortex shedding; the optimum height is 0.1 to 0.2 times the riser diameter. Otherwise, the drag force will be greatly increased. A moderate pitch can effectively change the position of the boundary layer separation and interfere with its axial correlation, typically five times the tube diameter.

A larger pitch will likewise lead to a substantial increase in drag force. The VIV suppression device can effectively reduce the fatigue damage caused by VIV.

4. Fatigue damage and fatigue life prediction

Fatigue life is the control parameter of the steel catenary riser design, its influence of many factors, so that the fatigue life prediction problem has become a difficult point in the design of the steel catenary riser. The influencing factors that have been identified are as follows: wave forces, flow, first-order response of the floating body, second-order response, and lift and sink motion. These influences cause fatigue damage at different locations in the steel catenary riser. Studies have shown that the top fatigue damage caused by second-order motion is much greater than first-order motion, shown in Figs. 8 and 9. By reducing

Steel Pipelines and Risers, Fig. 7 The AB pipe-soil model

Steel Pipelines and Risers, Fig. 8 Fatigue damage caused by first-order motion of vessel

the stiffness of the flexible joint, the fatigue damage at the top can be reduced.

The steel catenary riser introduced in this entry has become the first choice for deep-water oil and

gas development due to its low cost, high temperature, and high-pressure medium environment suitable for deep-water oilfield and strong adaptability to floating body movement. Foreign research and engineering experience show that,

Steel Pipelines and Risers, Fig. 9 Fatigue damage caused by first-order motion of vessel

with the help of buoyancy wave and riser tower structure, the applicable water depth of steel catenary riser and the tolerance of floating body movement can be further improved, which becomes a cost-effective solution for deep-water and very deep-water riser systems.

Top Tensioned Riser (TTR)

Top tensioned risers (TTRs) are dry tree riser solutions typically suited for a closely clustered well reservoir, wherein they provide surface access to subsea wells, thus allowing workover and reentry drilling from the host vessel during life of field. TTRs are challenging due to their complex and highly iterative design, weight control, and multiple complex interfaces between numerous equipment packages. The key design issues of TTRs are focused around the parameters that influence the riser strength, fatigue, and clearance response as well as their configuration through the host vessel wallaby.

TTRs are vertical riser systems that require externally applied tension to maintain their structural stability. The top tension is also the primary method used to control the response of the riser. These riser systems are in tension over a part or all of their length. The required tension is provided by tensioner systems, buoyancy modules, or a combination of both. As implied by the name,

the external tension is applied near the top sections of these riser systems.

These risers are composed of several tubulars that are the extension of the well's casing and tubing strings. Some of the TTRs are used with fixed platforms or jackups and may look like free-standing risers in that no subsea wellheads are used. The top tension for these risers is required to provide additional stability to the riser system. The external tension for these risers is generally provided by nonmotion-compensating mechanical and/or hydraulic tensioners.

Subsea or marine wellheads are used with riser systems deployed from floating platforms. The subsea wellhead is normally considered to be the top of the well's high-pressure housing and is generally located about 3–5 m (10–15 ft) above the seafloor. The subsea wellheads are required to allow for the disconnection of the riser from the well. This disconnection capability is needed for emergency considerations and operational flexibility.

Historical Background

TTRs have an established track record for deep-water applications in the Gulf of Mexico (GoM), West Africa, and offshore Indonesia. TTRs have been in service on floating production systems from as early as 1984 when the Hutton tension

leg platform (TLP) was installed in the UK North Sea, in 486 ft. water depth. Since then, more than 30 dry tree production facilities have been installed using TTRs, with either a TLP or spar as the host vessel. The first TLP installation in the GoM was Shell Auger in 1994. While this development was in a water depth of only 2,860 ft., the technology has now been successfully extended into water depths exceeding 5,000 ft. The first spar installation in the GoM was Neptune in 1986 in 1,930 ft. water depth. The deepest spar installed to date is the Shell Perdido Spar in 8,000 ft. water depth in the GoM.

TTRs can be utilized for either production or drilling activities, and the key system components for the production and drilling TTR are described in following sections.

Production TTR

A production TTR consists of a section of vertical pipe supported at the vessel by individual tensioner systems and connected to the subsea wellhead via a tieback connector (Fig. 10).

The tensioner system provides global stability, controls the motion response of the riser, and ensures that positive effective tension is maintained at the base of the riser under all loading conditions.

One option to tension the TTR is using a hydropneumatic tensioner. Such a tensioner system may have either four (4) or six (6) cylinders/rods that are mounted into the TLP deck structure via various interfaces. The cylinder rod slides up and down relative to the cylinder barrel and provides the stroke for the tensioner system and maintains near constant tension. The cylinders and rods interface with the riser string via a tension ring that typically incorporates a concentric large pitch thread profile that is complementary to the threads machined onto the tension joint. The threaded section is incorporated to provide space out capability to accommodate riser installation stack-up tolerances. The tension joint interfaces with the tension ring and centralizer guide roller system. The centralizer guide roller at the tree deck elevation acts as the riser centralization point and provides lateral support. The roller guides are designed to accommodate lateral

loads imparted by the riser in all environmental conditions. Top tension may also be provided by air- or nitrogen-filled buoyancy cans attached to the upper section of the TTR. In contrast to the hydropneumatic tensioners, buoyancy cans provide tension passively and minimize the interaction between the host vessel and TTRs.

Production TTRs are typically dual casing risers that have outer and inner riser strings. Production tubing is run through the inner riser to transfer production fluids to the production vessel. The production tubing is entirely supported from the surface tree body, with no hanger at the mudline.

The inner production riser is supported from the surface wellhead with a casing hanger and connects in the subsea wellhead with an internal tieback connector (ITBC). The ITBC provides the interface between the inner riser and the subsea wellhead assembly or the external tieback connector (ETBC). The ITBC must resist the tension overpull/preload that will be applied to the inner riser prior to setting the adjustable casing hanger in the surface wellhead. The ITBC contains a lockdown sub, which when rotated by a running tool, locks into the subsea wellhead housing or ETBC. The ITBC interface with the production inner riser joints is via a premium casing thread. The annulus between the inner riser and outer casing may be filled with a thermal barrier gel to maintain production fluid temperatures during operation, while the annulus between the inner casing and tubing is filled with brine for most operations.

Outer riser joints for the production risers extend from the tension joint to the stress joint assembly above the subsea wellhead. Outer riser pipe can be straked to suppress vortex-induced vibration (VIV) motion under current loads. The lower stress joint connects the riser to the subsea casing system at the subsea wellhead via the ETBC. The ETBC provides the interface between the outer riser and the subsea wellhead and must accommodate the tension and high bending loads imposed by the riser. The ETBC may be integral or flanged to the lower stress joint. The stress joint is used to manage the high bending stresses and fatigue loading at this localized section adjacent to the point of fixity at the seabed.

Steel Pipelines and Risers, Fig. 10 Typical production top tensioned riser schematic. (© 2H Offshore Inc.)

On a TLP, a guide wire system may be utilized during riser installation to direct the production TTR to the target wellhead and ensure no interference with adjacent structures.

Drilling TTR

Drilling risers (Fig. 11) deployed from host vessels include a surface blowout preventer (BOP) stack to contain the pressure in the wellbore.

Therefore, the riser pipe needs to be designed to accommodate the incidental wellbore pressure. Drilling operations may be conducted through a single casing outer riser or through a drilling inner riser for dual casing configurations.

Similar to the production TTRs, the drilling TTR is supported on the host vessel by a tensioner system, which may be standardized to be identical

Steel Pipelines and Risers, Fig. 11 Typical drilling top tensioned riser schematic. (© 2H Offshore Inc.)

to the production tensioner or customized to accommodate the higher tension requirements for the drilling TTR. Non-standardized tensioner systems may include additional tensioner cylinders at the tensioner deck or a supplementary tensioning system at a separate deck level to meet the top tension requirements for the drilling TTR.

Outer riser joints may be seam-welded pipe sections with connectors welded at either end to form a continuous riser joint. The exterior of the outer riser joints is coated with thermal-sprayed aluminum (TSA) for corrosion protection. Thick-wall outer riser joints that are neoprene coated may be used in the splash zone to provide extra corrosion and impact protection. Buoyancy

modules may be attached to a section of the drilling outer riser, below the high current region, to reduce the loads on the tensioner system.

Similar to production TTRs, precision machined forgings, with profiles optimized to accommodate the high strength and fatigue loads at TTR interfaces with the vessel and the mudline, are located at the upper and lower ends of the drilling riser in the form of the tension joint and stress joint assemblies, respectively. The stress joint assembly connects and seals to the high-pressure housing on the subsea wellhead via the ETBC. Similar to production TTRs, fairings and strakes may be utilized as VIV suppression devices to reduce fatigue damage caused by riser VIV.

The drilling inner riser, if used, is installed inside the drilling outer riser and is suspended with a casing hanger that lands inside the drilling surface wellhead. At the base of the drilling inner riser is an ITBC that latches inside the subsea wellhead housing. The drilling inner riser is made concentric to the drilling outer riser by the use of centralizers.

TTR VIV and VIM Response

In the absence of suppression measures, VIV of TTRs may be a significant contributor to fatigue damage and may dictate the design of such risers. Suppression devices such as strakes and fairings are used in high current environments to mitigate VIV. Fairings offer the additional benefit of reducing drag on the TTR.

The fatigue response of the TTR to vortex-induced motions (VIMs) of the hull also needs to be considered during design. The hull VIM response is independent of water depth and may be more onerous for TTRs deployed in shallow water depths (the large ratio of the VIM amplitude to water depth results in higher cyclic bending loads at the base of the TTR).

Installation and Commissioning Considerations

The first consideration in any TTR installation campaign is the evaluation of environmental conditions to determine whether weather conditions are acceptable to complete the TTR installation.

There are many tools available to aid this evaluation and equipment to monitor real-time conditions for this assessment.

To land the riser on the subsea wellhead, a method of guiding the riser is required, which varies based on the vessel type. For dynamically controlled semisubmersible vessels, the riser can be guided by adjusting the position of the vessel using the dynamic positioning (DP) thruster system. This provides for large adjustment and good accuracy. A spar platform can guide the riser using the vessel mooring system; for TLPs, there is no means of controlling the vessel position so a dedicated guide wire system is utilized to guide the riser base to the desired subsea wellhead. A guide wire system generally has a winch or multiple winches on the vessel with wire rope connected to a structure on the subsea wellhead. A guide arm structure clamped to the riser base connects the riser to the guide wire. The riser is guided to the subsea wellhead using increased tension in the guide wire as the riser approaches the wellhead.

A TTR can be installed from different offshore platform types, but a drilling rig is always required to perform the installation work. The drilling rig uses many tools to install a TTR, and consideration of the tool interfaces with the riser equipment must be evaluated to ensure that the equipment can perform the job as intended. Riser equipment will be staged on an available deck or stacked up vertically in a pipe rack depending on riser pipe size or vessel design/duty. Riser pipe is typically lifted to the drill rig floor using the platform crane and presented to a joint handling device in the horizontal position, and the joint is then lifted to the vertical position using an elevator type design to hold the joint and position it over the rotary opening.

The joint is then lowered through the drill rig floor and landed in a securing system in the rotary with the upper connection of the joint presented upward for the connection of the next joint. The riser connections will be either a casing-type design that requires the use of makeup power tongs to torque the threaded connections to the required value or a flange-type design that requires tensioning of studded connections on

the flange to achieve a required preload. These operations are performed at the rig floor when the next joint is presented to the rotary, and subsequent joints are run repeating the same steps.

The taper stress joint with ETBC is designed to connect to the subsea wellhead or subsea equipment stacked on the wellhead. Standard outer riser joints make up the majority of the riser length. Once all standard outer joints are connected, provision can be made to perform a space out exercise either by running more joints or by lowering the riser on drill pipe to the subsea wellhead; this operation confirms the length between the vessel and subsea wellhead for comparison to calculated values. Once elevations are confirmed, the riser installation is completed by running a selected number of pup joints to correctly space out the riser followed by the tension joint.

With the tension joint connected and the full riser string hanging from the drill rig, the riser can be lowered and connected to the subsea wellhead. Typically, connection is made using an ROV for visual monitoring and hydraulic actuation of the connection system. With the riser connected to the subsea wellhead, the riser can be tensioned to the required top tension for engagement of the tensioner system. Once engaged, the riser tension can be handed from the rig to the tensioner system by increasing the tension through the tensioner system and decreasing the hook load.

With the outer riser fully supported on the tensioners, the riser is ready to begin surface equipment installation. For a single casing drilling riser, typically a wellhead spool and BOP system are attached to the top of the tension joint and tested to confirm surface equipment and riser integrity before drilling operations commence.

For dual riser systems, a surface wellhead spool is attached to the top of the tension joint prior to running inner riser joints. Inner riser joints are installed using the same method as outer joints, and the first inner joint is capable of latching and sealing into a profile within the subsea wellhead to isolate the inner riser from the outer annulus. Once all inner riser joints are run and spaced out correctly to match the outer riser length, the inner riser can be tensioned to the

required value and latched and sealed into a profile within the surface wellhead. Some adjustment of tension through the tensioners may be required to support the additional load of the inner riser.

For a drilling riser, a BOP system can be attached to the top of the wellhead and tested to confirm riser integrity before drilling operations commence. For production risers with surface equipment, a surface tree is installed on top of the wellhead and a BOP system connected to the top of the tree. With the BOP system in place, the riser has well control barriers to begin running tubing downhole and perform well completion operations to bring the well online.

Additional installation activities required before full production are the installation of control lines to the riser system through a control umbilical system supported between topsides and the top of the riser. A flexible jumper is also required to convey fluid between tree and topside production manifold.

Steel Pretreatment

Rui Li
School of Naval Architecture and Ocean
Engineering, Dalian University of Technology,
Dalian, China

Definition

Marine steel, through the process of rolling transportation and stacking, often rusts, deforms, and is covered with various oil stains and impurities, and the direct usage of which will result in not only the reduction of steel performances but also poor processing accuracy and low production speed. Therefore, the open-air stacked steel must go through the steel pretreatment procedures in order to be used for hull components processing (Liu et al., 2011).

Introduction

Steel Pretreatment Assembly Line

The steel pretreatment automatic assembly line refers to the automatic operation assembly line composed of steel transportation, leveling and

straightening, rust removal, primer coat spraying, drying, and other procedures, which is categorized into two types: steel plate pretreatment assembly line and profile pretreatment assembly line. There are also cases of the treatment of both steel plate and profile on the same production line. This introduction is mainly about the steel plate pretreatment assembly line (Xu, 2005).

The technological process and main equipment of the steel plate pretreatment assembly line are shown in Fig. 1:

- (1) In the steel yard, the steel is first lifted onto the roller table by a crane or an automatic loading truck, as shown in the Fig. 2.
- (2) The roll table passes the steel to a multi-roll leveler and flattens the plate, as shown in the Fig. 3.
- (3) Some steel plate pretreatment assembly lines are equipped with preheating devices and spraying devices. The leveled steel plate is sent to the preheating device by the conveying table roller, and the temperature of the steel plate reaches 40 °C ~ 60 °C. The purpose of preheating is to remove the moisture on the surface of the steel plate and loosen the oxide scale and rust spots for later removal and to improve the adhesion of the paint film. The

Steel Pretreatment, Fig. 1 Technological process and major equipment of steel pretreatment assembly line

purpose of the spraying device is to remove salt from the surface of the steel plate.

- (4) The steel plate enters the procedure of impeller blasting rust removal, with the shot blasting device automatically throwing shots to both sides of the steel plate (the

Steel Pretreatment, Fig. 2 The roller table

Steel Pretreatment, Fig. 3 The multi-roll leveler

Steel Pretreatment, Fig. 4 The shot blasting machine

shots can be recycled and reused), and hot air removing the dust on the surface of the steel plate. Figures 3 and 4 respectively show the steel plate before entering the shot blasting machine and the steel plate after rust removal.

- (5) After rust removal and cleaning, the steel plate enters the spraying chamber where the maintenance primer coat is sprayed. Spraying operations are carried out in a semi-enclosed spray chamber, as shown in Fig. 5. To adapt to steel plates of different widths, the round-trip distance of the spray gun can be adjusted. In order to maintain continuous coating and a certain film thickness, the conveying speed of the roller should be in line with the spraying speed of the spray gun, which can be adjusted through electrical control.
- (6) After leaving the spraying chamber, the steel plate is dried in the drying chamber. The film

Steel Pretreatment, Fig. 5 The spraying chamber

Steel Pretreatment, Fig. 6 The drying process

Steel Pretreatment, Fig. 7 The processing workshop

drying methods include infrared rays, far infrared rays, and electric heating, all of which require a ventilation device to facilitate the evaporation of the paint solvent and to speed up the drying process, as shown in Fig. 6.

- (7) After being dried, the plate leaves the drying chamber and is sent out of the pretreatment assembly line through the high-speed roller table and into the processing workshop for the marking off and processing after passing the quality inspection, as shown in Fig. 7.

It should be noted that since the rust removal chamber and spray chamber are filled with iron dust and spray, to maintain a good working environment and to prevent the diffusion of harmful gases into the open air, special attention should be paid to dust collection, ventilation, and explosion prevention, and the corresponding environment protection

measures and the fire and explosion prevention measures should be taken (Huang, 2013).

Steel Leveling and Straightening

The steel plates and profiles used in shipbuilding, due to the uneven rolling and uneven cooling contractions after rolling, and various factors during transportation and storage, often have waves, local concavities, and distortions. These deformations will affect the normal marking-off, gas cutting, and other machining procedures, and reduce machining accuracy (Shu et al., 2013). In addition, these deformations may also cause additional stress or component instability during welding, thus affecting the strength of components. Therefore, the steel plates should be leveled and straightened to eliminate these deformations. In the shipyard, the deformations of the steel plates are usually leveled and straightened by a multi-roll leveler, and the deformations of profiles by a profile leveler.

Steel Plate Leveling and Straightening

The deformation of a steel plate is caused by that some fibers are turning shorter or longer than others. Therefore, plate leveling and straightening is actually shortening the longer fibers or lengthening the shorter fibers so that these fibers are at the same length with their surrounding ones, but in reality, the method of lengthening fibers is often adopted because of the difficulty to compress fibers.

A leveler commonly used in a shipyard is composed of two rows of working rollers, which often consist of 5–11 working rollers, as shown in Fig. 8. The lower row is the row of active shaft rollers, which is fixed on the machine body by bearings and cannot be adjusted at all, and the rotation of which is driven by the motor through the speed reducer. The upper row is the row of driven shaft rollers. The vertical gap between the upper and lower rollers can be adjusted by the manual screw or the electric adjusting device for leveling steel plates of various thicknesses. When being leveled, the plate gets in between with the rotation of the rollers and is subjected to multiple alternating small curvature bendings from opposite directions between the upper and lower

Steel Pretreatment, Fig. 8 The leveler machine

Steel Pretreatment, Fig. 9 The leveling machine with the upper and lower rollers parallel

rollers, where plastic deformations are generated as the bending stress exceeds the yield limit of the material. Thus, shorter fibers are lengthened and the plate is leveled.

Multi-roll levelers, according to the different arrangements of the rollers and the positions of the adjustable rollers, can be divided into two types: multi-roll levelers with the upper and lower rollers parallel and separately adjustable (Fig. 9), and the leveling machines with the upper and lower rollers unparallel (Fig. 10).

Profile Leveling and Straightening

The profile is mainly leveled and straightened by the profile straightener. Fig. 11 shows the working principles of the profile straightening machine, which consists of two supports and a push support. The two supports have no power transmission, but the distance between them can be adjusted according to the need. The push support is installed on a sliding block, which is capable of horizontal reciprocating movements driven by a

motor through a speed reducer. During profile straightening, the deformation section of the profile is set between the two supports and is deformed in the opposite direction by the force of the pushing support, and thus the profile is straightened.

In the absence of special profile leveling and straightening equipment, small profiles can be leveled and straightened by manual tapping on platforms or round piers; large profiles can be leveled and straightened using flame heating and water cooling method or with hydraulic press machines, and it is necessary to configure compression modules in accordance with the profile shape when using hydraulic press machines (Kennedy et al., 2004).

Surface Cleaning of Steel

Steel surface cleaning refers to the procedure of removing the oxide scale, rust, and other impurities on steel surface (generally referred to as rust removal), and then spraying a protective primer coat. The common methods of steel surface cleaning involve manual rust removal, mechanical rust removal (rust removal of shot blasting and rust removal of impeller blasting), chemical rust removal, hydro blasting rust removal, etc. At present, the widely adopted methods in steel pretreatment are rust removal of impeller blasting and chemical rust removal.

Steel Pretreatment,**Fig. 10** The leveling machine with the upper and lower rollers unparallel**Steel Pretreatment, Fig. 11** The profile straightening machine**Steel Pretreatment, Fig. 12** Basic form of shot blasting machines**Rust Removal of Impeller Blasting**

Rust removal of impeller blasting is one of the rust removal methods in which iron shots or other abrasives are flung onto the surface of steel at high speed to remove oxide scale and rust spots.

The shot blasting machines in use now are mostly horizontal, as shown in Fig. 12, and the steel can be directly transmitted into them through the raceway so that automatic assembly lines can be set up easily. When horizontal shot blasting machines are used to remove rust, the iron shots are easily spread on the upper surface of the steel plate, so it is necessary to set up high-pressure blowers or mechanical scrapers to momentarily remove the iron shots on steel plates.

Generally, shot blasting machines are equipped with a shot recycling system to facilitate the recycling of shots, and a ventilation and dust removal device to reduce their environmental pollution (Nguyen and Oterkus 2020).

Chemical Rust Removal

Chemical rust removal usually refers to a multi-step pickling process, with the basic process as

follows. After being degreased and washed, the steel is placed in the pickling tank, where the oxide scales and rust spots are removed. After water washing, the residual acid is neutralized with lye to prevent corrosion of the steel, and then the steel is rinsed with water. In chemical rust removal, hydrochloric acid, sulfuric acid, phosphoric acid, or a mixture of them is often used as a rust removal solution.

Structural Analysis and Design of VLFS

Kazuhiro Iijima

Department of Naval Architecture and Ocean Engineering, Osaka University, Osaka, Japan

Definition

The dominant load to very large floating structure (VLFS) is the hydrodynamic load by ocean waves. The wave loads on VLFS may be altered due to the structural deformation of VLFS, which is the so-called hydroelasticity effect. It is important to proceed the structural design of VLFS while performing and using the hydroelasticity analysis in parallel. The structural design is thus combined with analysis. This article illustrates how the hydroelasticity analysis of different levels may be incorporated into the structural design of VLFS, by classifying the process into initial design stage, scantling stage, and evaluation stage.

Scientific Fundamentals

Key Concept

VLFS has large dimensions in horizontal directions compared with that in depth-wise. The structure is flexible to deform under wave actions, and the magnitude of the deformation can be equivalent to or exceed that of the rigid body motions. The flexible deformation characterizes the response of VLFS. Figure 1 shows a schematic comparison of the response between a conventional rigid ship and VLFS subjected to a point load (Suzuki and Yoshida 1995). The rigid ship bears the force and moment due to the point load by the increase of the translational and angular displacements, while VLFS distributes the load along the structure by the deformation mechanism; VLFS deforms and interacts with the surrounding static/dynamic pressure fields. This makes the hydroelasticity theory play the role. In the structural analysis and design of VLFS, how to

Structural Analysis and Design of VLFS, Fig. 1 Rigid body motion vs flexible deformation to a point load. (Reproduction from Suzuki 1995)

consider the hydroelastic effect at as early stage as possible is the key issue (Suzuki et al. 2006).

Structural Analysis Method

Primary, Secondary, and Tertiary Response

Discussion starts with the structural analysis of conventional ship structure. The structural stress in a ship may be classed into “primary,” “secondary,” and “tertiary” stresses. These structural stress types may be evaluated separately and superposed together to give a picture of the stress distribution within the structure. The analysis method and the structural model depend on the stress levels to be considered. The primary stress is the longitudinal stress due to hull girder deformations when the ship hull girder is regarded as a ship beam. The longitudinal stress may be understood and analyzed by adopting a beam theory. The load to the beam model may be evaluated by the rigid body motion analysis together with hydrodynamic theories. The so-called strip theory is used to this end. The hydrostatic/hydrostatic pressure and inertial loads which are balanced among themselves can be evaluated and given to the beam model to find the sectional loads such as vertical bending moment.

The secondary stress is the stress due to the transverse deformation when the structure is subjected to loads such as static/dynamic pressure, internal pressure, etc. For example, the double bottom structure may deform to the pressure as a whole. This type of stress may be analyzed by using a so-called hold model with the pressure applied on the structure. The hold model is usually a three-dimensional finite element (FE) model including the transverse structural members such

as girders/floors, transverse frames, double bottom, etc. Usually, the shell and beam elements are used for the modeling, and the membrane stress is only referenced. The tertiary stress is the local bending stress due to the local pressure. The local pressure may include static/dynamic/internal/external ones such as panting, slamming, heavy concentrated weight, etc. The local stress is applied to the local model (e.g., stiffened plate model).

Structural Analysis of VLFS

When one regards that the above classification applies to the analysis of VLFS, too, the only one big difference from that of ship structure is found to be the evaluation of the hull girder (primary) stress of VLFS. The hydroelasticity theory should be applied to the prediction of the primary stress in VLFS (Suzuki 2006; Iijima 2018). The structural model for the hydroelasticity analysis can be a beam grillage which model the whole VLFS (Fig. 2, left). When one considers about the large horizontal plane of VLFS, it is also an idea to use the plate model based on plate theory (Fujikubo and Yao 2001). However, at least, the anisotropic plate model is recommended to be used for the structural analysis to account for the anisotropic properties of the structure; the structure may exhibit different deformations between the longitudinal and transverse bending, due to the difference of girder arrangements in longitudinal and transverse directions, respectively.

Further, the sandwich grillage model (Fig. 2, right) is advantageous over the beam grillage model in a point that it can represent the torsional deformation correctly. The shell FE model (Fig. 3) is the other choice. It should be pointed out,

Structural Analysis and Design of VLFS, Fig. 2 Grillage model and sandwich grillage model. (Taken from Fujikubo and Yao 2001)

Structural Analysis and Design of VLFS, Fig. 3 Shell model. (Taken from Seto et al. 2003)

however, that the detailed modeling consumes time both in terms of model preparation and analysis, and detailed information is not available at the early design stage. The pressure for the evaluation of the secondary stress is also imported from the hydroelasticity analysis which is used for the evaluation of the primary stress in VLFS.

Table 1 compares the structural analysis between ship structure and VLFS. This procedure may be termed as “two-step” method in which the hydroelasticity analysis is performed firstly; then primary and secondary stress are evaluated. It is similar to the “two-step” method for ship structure, in which the rigid body motion analysis with

Structural Analysis and Design of VLFS, Table 1 Structural stress level, structural model, and applied load used for the direct analysis and design: ship structure vs VLFS

	Ship structure	VLFS
Load analysis	Rigid body motion + hydrodynamic theory, e.g., strip theory	Flexible body deformation + hydroelasticity theory
Primary stress	Beam model under the pressure/inertia evaluated by using the load analysis	Hydroelasticity theory + beam assumption
Secondary stress	Three-dimensional shell FE model under the pressure/inertia evaluated by using the load analysis	Three-dimensional shell FE model under the pressure/inertia evaluated by using the load analysis
Tertiary stress	Local structural model under the local load	Local structural model under the local load

hydrodynamics is performed firstly; then subsequent analyses are made (Oka et al. 2002).

There is the other method: “one-step” method (Seto 2003). In this method, the primary stress and secondary stress are evaluated simultaneously. The shell FE model may be used seamlessly between the primary stress analysis and the secondary stress analysis. The primary and secondary stress may be simultaneously evaluated, then. The one step method should be useful at the late design stage for confirming the stress level more accurately.

Structural Design of VLFS

Structural Design Formula for VLFS Taking Account of Hydroelasticity

Objectives The design process inevitably follows the so-called design spiral for optimization. When the structural design of ship is revisited, one may notice that design loads are usually used, instead of the direct motion-load analysis. The designer can easily know the design hull girder loads once the main particulars of the ship is determined, which facilitates the convergence of the design spiral. For the structural design of VLFS, it is important to consider the hydroelastic effect even at the preliminary design stage, as early as possible in place of using design loads for VLFS. The hydroelastic behavior can be evaluated only after the main particulars and structural design scantlings are fixed (because it is a fluid-structure interaction problem), and the structural data necessary for the hydroelasticity analysis have become available. It is thus required to develop such a formula to roughly estimate the hydroelastic effect based on

several design parameters such as size of structure, stiffness of structure, etc.

Theoretical Background When one considers VLFS with uniform mass, stiffness, and shape, the VLFS may be modeled to a uniform beam on an elastic foundation. This simple model applies to both semi-submersible type (e.g., MOB) and pontoon type (Mega-Float) VLFS. The hydrodynamic interactions among the floaters are neglected, herein. The objective of setting up this simple model is to derive the parametric dependencies. When it is subjected to a regular wave with the circular frequency ω and with the wave height H , the governing equation in Eq. (1) is given from the force equilibrium among loads on a strip with unit length. The vertical deflection w is taken upward and the x axis along the VLFS with the center of the origin at the midship. The variable k denotes the wave number of the incident wave.

$$(m + m_a) \frac{\partial^2 w}{\partial t^2} + c \frac{\partial w}{\partial t} + EI \frac{\partial^4 w}{\partial x^4} + k_c w = F_z \cos(kx - \omega t) \quad (1)$$

where m is the mass per unit length, m_a the added mass per unit length, c the damping force coefficient per unit length, EI the bending rigidity, k_c the restoring force coefficient per unit length, and F_z the force amplitude per unit length which is proportional to the wave height H . The value of these variables can be regarded constant here by following the assumption of the uniformity even though they could be a function of time and space in reality.

The solution to Eq. (1) may be given by a sum of a particular solution and homogeneous solutions (Suzuki and Yoshida 1995). The homogeneous solutions to Eq. (1) give a large contribution to the behavior near the both ends, however, decay exponentially towards the inner part of the structure from the ends. This implies that the effect of disturbance at the ends decays quickly with the distance from the disturbance. The disturbance is distributed over a length. This length is called “characteristic length” and discussed in the next paragraph. The particular solution is then more relevant when discussing the design parameters. The analytical solution by this approach gives a good insight into the hydroelastic behavior of a VLFS.

The particular solution w_p to Eq. (1) is given in Eq. (2). The damping term is dropped here for simplicity.

$$w_p(x) = \frac{F_z}{-(m + m_a)\omega^2 + EI k^4 + k_c} \cos(kx - \omega t) \quad (2)$$

Characteristic Length and Maximum VBM The length over which the effect of disturbance decays and averaged is defined as a characteristic length λ_s (see Fig. 1) and given by a simple formula in Eq. (3).

$$\lambda_s = 2\pi \sqrt[4]{EI/k_c} \quad (3)$$

For a frequency region lower than a heave natural frequency given as $\sqrt{k_c/(m + m_a)}$, the inertia term or the first term in the denominator of Eq. (2) is negligible; then the vertical bending moment (VBM) obtained from Eq. (2) reduces to Eq. (4).

$$\begin{aligned} M &\approx -EI \frac{\partial^2 w_p}{\partial x^2} = EI \frac{k^2}{EI k^4 + k_c} F_z \cos(kx - \omega t) \\ &= EI \frac{1}{\left(k \sqrt{EI/k_c}\right)^2 + 1/k^2} \frac{F_z}{k_c} \cos(kx - \omega t) \\ &\leq 2\pi^2 EI \frac{1}{\lambda_s^2} \frac{F_z}{k_c} \approx \pi^2 EI \frac{H}{\lambda_s^2} \end{aligned} \quad (4)$$

In the above, the vertical force amplitude F_z is approximated rather conservatively to a product

of the restoring force coefficient k_c and the wave amplitude $H/2$ (times the breadth) in the low-frequency region. The vertical bending moment takes a maximum value determined by the wave height H , the bending rigidity EI , and the characteristic length λ_s , and it is attained when the incident wave length $2\pi/k$ is equal to the characteristic length λ_s , irrespective of the length of the VLFS. It is interesting to note that the characteristic length which firstly has been introduced as the length over which the disturbance is distributed is also related to the maximum vertical bending moment in VLFS. Equation (4) is applied to the prediction of VBM in VLFS which has the length sufficiently larger than the characteristic length.

Structural Design Flow of VLFS

The structural design flow of VLFS can be summarized as follows (see Fig. 4):

- (i) Initial planning
- (ii) Structural arrangement of large structural members, e.g., floors and girders, with a consideration of Eq. (4), or hydroelasticity analysis using plate model
- (iii) Structural modeling using grillage or sandwich grillage model
- (iv) Hydroelasticity analysis (simulation)
- (v) Initial check performance and stress, initial design stage
- (vi) Scantling of structural members, e.g., longitudinal stiffeners, frames, and transverse members
- (vii) Structural modeling including all the members
- (viii) Detailed analysis for transverse members taking account of hydroelasticity. One-step (hydroelasticity analysis) or two-step method (static analysis)
- (ix) Check performance and stress, scantling check stage
- (x) Safety check and evaluation (ultimate strength, Tsunami, damaged condition, etc.)

The items ii–iv and vi–viii are looped until the design converges.

What is special about the design of VLFS is that the numerical analysis based on

Structural Analysis and Design of VLFS, Fig. 4 Design flow for VLFS (Reproduction from JASNAOE Committee 2004)

hydroelasticity theory is required for all the stages of design. One may call it “Design-by-Analysis,” while that for ship is “Design-by-Rule.” The

hydroelasticity analysis is used both in initial design check and final design check. At the final safety evaluation stage, safety margin to the

extreme loads (e.g., extreme weather, tsunami) and redundancy of the system (damaged condition) must be checked. The safety margin may be evaluated by performing nonlinear structural analysis such as ultimate strength analysis. Buckling, yielding, and rupture of the structural members should be considered.

Sometimes, the final safety evaluation may be done with the use of reliability theory, or probability of failure. The target safety level of VLFS is another issue. Some studies are done in the past and may be consulted with Suzuki (2001).

Synonyms

[Structural mechanics of polar engineering](#)

Definition

Structural characteristics of polar engineering mainly refer to the deformation, stress, and strain of the polar structure under the load of sea ice. According to the polar structural characteristics, the structural strength may be determined so as to prevent them from damage or accidents.

Scientific Fundamentals

Design Scenario and Development of Design Loads

The design scenario forming the basis of the ice loads for plating and framing design is a glancing collision on the shoulders of the bow, see Figs. 1 and 2 (Daley 2000). In this scenario, the ship is assumed to be moving forward at the design

Structural Characteristics of Polar Engineering, Fig. 1 Design scenario – glancing collision on shoulder (Daley 2000)

speed, striking an angular ice edge. During the collision, the ship penetrates the ice and bounces off. The ship speed, ice thickness, and ice strength are assumed to be class dependent. The maximum force can be calculated by equating the normal kinetic energy with the energy used to crush the ice. The ice crushing force cannot exceed the force required to fail the ice in bending. The force limit due to bending is determined by the angles, ice strength, and also the thickness.

The rule scenario is strictly valid only for the bow region and for the stern of double-acting ships. In order to produce a balanced structural design, loads on other hull areas are set as a proportion of the bow area by using empirical hull area factors (Kendrick et al. 2007). The loads on other hull areas are not strongly dependent of the bow angles, and so bow loads are normalized using a “standard” set of bow angles when applied elsewhere.

Another operational scenario involves a collision on the midbody. Two cases are considered here. In the first case, the vessel gains a lateral velocity due to an impact at the bow (Daley and Kendrick 2008; see Fig. 3 below). The midbody impact may occur immediately after the bow collision or be somewhat delayed, depending on the amount of sea room between the ship and the second impact.

In this scenario, the impact velocity in the midbody will be a function of the initial bow impact magnitude and location, and of the time lag between the first and second impacts, depending on the channel width or distance between ice floes. Here the second impact is assumed to take place at the mid-ship so that the influence of the yaw (turning) velocity can be ignored.

A second case of glancing impact results from turning in a channel (Daley and Kendrick 2008; see Fig. 4 below). In this case the impact velocity depends on the turning rate, and will be higher aft of amidships. For vessels with a better turning ability, for instance, those equipped with azimuth thrusters, special attention should be given for this scenario.

The discussion hereafter will focus on the case of collision with a reflected impact but the results and conclusions can also be applied to the case of turning collision.

The design loads are obtained in several steps. First, the total load is found as the minimum of the crushing and flexural limiting loads for the design ice. Then, the patch over which this load is applied is determined and idealized. Finally, the distribution of load within the patch is modified to account for the local loading peaks.

Structural Characteristics of Polar Engineering, Fig. 2 Design scenario – flexural failure during glancing collision (Daley 2000)

Structural Characteristics of Polar Engineering, Fig. 3 Bow-midbody glancing sequence – (a) immediate, (b) delayed (Daley and Kendrick 2008)

Structural Characteristics of Polar Engineering, Fig. 4 Midbody glancing during a turn (Daley and Kendrick 2008)

Structural Requirements for Polar Class Ships

Hull Areas

The hull of polar class ships is divided into areas reflecting the magnitude of the loads that are expected to act upon them. In the longitudinal direction, there are four regions: bow, bow intermediate, midbody, and stern. The bow intermediate, midbody, and stern regions are further divided in the vertical direction into the bottom, lower, and icebelt regions (IACS Req. 2011; see Fig. 5 below).

The upper and lower ice waterlines on which the design of the vessel has been based is to be indicated in the classification certificate. The upper ice waterline (UIWL) is defined by the maximum draughts fore, amidships, and aft. The lower ice waterline (LIWL) is to be defined by the minimum draughts fore, amidships, and aft.

The lower ice waterline is determined with due regard to the vessel’s ice-going capability in the ballast loading condition (e.g., propeller submergence).

At no time is the boundary between the bow and bow intermediate regions to be forward of the intersection point of the line of the stem and the ship baseline. The aft boundary of the bow region need not be more than 0.45 L aft of the forward perpendicular (FP). The boundary between the bottom and lower regions is to be taken at the point where the shell is inclined by 7° from the horizontal plane. If a ship is intended to operate astern in ice regions, the design of aft section of the ship should also satisfy the bow and bow intermediate hull area requirements.

Shell Plate

The required minimum shell plate thickness, t , is given by:

$$t = t_{net} + t_s \text{ [mm]} \tag{1}$$

where

t_{net} = plate thickness required to resist ice loads
 t_s = corrosion and abrasion allowance
 t_{net} , depends on the orientation of the framing (IACS Req. 2011; see Fig. 6 below).

Framing

Framing members of polar class ships are to be designed to withstand the ice loads. The term

Structural Characteristics of Polar Engineering, Fig. 5 Hull area extents (IACS Req. 2011)

“framing member” refers to transverse and longitudinal local frames, load-carrying stringers, and web frames in the areas of the hull exposed to ice pressure (IACS Req. 2011; see Fig. 5), where the load-distributing stringers have been fitted; the arrangement and scantlings of these are to be meet the requirements of each member society.

The strength of a framing member is dependent of the fixity that is provided at its supports. Fixity can be assumed where framing members are either continuous through the support or attached to a supporting section with a connection bracket. In other cases, simple support is to be assumed unless the connection can be demonstrated to provide significant rotational restraint. Fixity is to be ensured at the support of any framing which terminates within an ice-strengthened area.

The details of framing member intersection with other framing members, including plated structures, as well as the details for securing the ends of framing members at supporting sections, are to be in accordance with the requirements of each member society.

The design span of a framing member is to be determined on the basis of its molded length. If brackets are fitted, the design span may be reduced in accordance with the usual practice of each member society. Brackets are to be configured to ensure stability in the elastic and post-yield response regions.

When calculating the section modulus and the shear area of a framing member, net thicknesses of the web, flange (if fitted), and attached shell plating are to be used. The shear area of a framing

Structural Characteristics of Polar Engineering, Fig. 6 Shell framing angle (IACS Req. 2011)

member may include that material contained over the full depth of the member, i.e., web area including portion of flange, if fitted, but excluding attached shell plating.

The local frames in transversely framed side structures and in bottom structures (i.e., hull areas BIb, Mb, and Sb) are to be dimensioned such that the combined effects of shear and bending do not exceed the plastic strength of the member. The plastic strength is defined by the magnitude of midspan load that causes the development of a plastic collapse mechanism.

Side longitudinals are to be dimensioned such that the combined effects of shear and bending do not exceed the plastic strength of the member. The plastic strength is defined by the magnitude of midspan load that causes the development of a plastic collapse mechanism.

Web frames and load-carrying stringers are to be designed to withstand the ice load patch as defined in I2.3. The load patch is to be applied at locations where the capacity of these members under the combined effects of bending and shear is minimized.

Plated Structures

Plated structures are those stiffened plate elements in contact with the hull and subject to ice loads.

These requirements are applicable to an inboard extent which is the lesser of:

- (i) web height of adjacent parallel web frame or stringer
- (ii) 2.5 times the depth of framing that intersects the plated structure

The thickness of the plating and the scantlings of attached stiffeners are to be such that the degree of end fixity necessary for the shell framing is ensured. The stability of the plated structure is to adequately withstand the ice loads.

Longitudinal Strength

Ice loads need only be combined with still water loads. The combined stresses are to be compared against permissible bending and shear stresses at different locations along the ship's length. In addition, sufficient local buckling strength is also to be verified.

The strength criteria provided in Table 1 are to be satisfied (IACS Req. 2011). The design stress is not to exceed the permissible stress.

Local Details

For the purpose of transferring ice-induced loads to supporting structure (bending moments and

Structural Characteristics of Polar Engineering, Table 1 Longitudinal strength criteria (IACS Req. 2011)

Failure mode	Applied stress	Permissible stress when $\sigma_y / \sigma_u \leq 0.7$	Permissible stress when $\sigma_y / \sigma_u > 0.7$
Tension	σ_a	$\eta \sigma_y$	$\eta \mathbf{0.41} (\sigma_u + \sigma_y)$
Shear	τ_a	$\eta \sigma_y / (3)^{0.5}$	$\eta \mathbf{0.41} (\sigma_u + \sigma_y) / (3)^{0.5}$
Buckling	σ_a	σ_c for plating and for web plating of stiffeners $\sigma_c / \mathbf{1.1}$ for stiffeners	
	τ_a	τ_c	

where

σ_a = applied vertical bending stress [N/mm²]

τ_a = applied vertical shear stress [N/mm²]

σ_y = minimum upper yield stress of the material [N/mm²]

σ_u = ultimate tensile strength of material [N/mm²]

σ_c = critical buckling stress in compression [N/mm²]

τ_c = critical buckling stress in shear [N/mm²]

$\eta = 0.8$

shear forces), local design details are to comply with the requirements of each member society.

The loads carried by a member in way of cutouts are not to cause instability. Where necessary, the structure is to be stiffened.

Key Applications

Stiffness Curves Used for Structural Design and Verification of a Typical Icebreaker

To properly understand the structural interaction of icebreaker grillage section components, LR has used nonlinear finite element methods to compute the characteristic stiffness curve well into plasticity. The characteristic stiffness curve is considered representative of the effective structural interaction of the section components and has been found to relate directly to the section design methodology (elastic or plastic). Pearson et al. (2015) analyzed a set of existing icebreaking vessels and presented a simple acceptance criterion that requires the structure to carry at least 150% of the design load before reaching a plastic strain of 2.5%.

An Acceptance Criterion for Evaluation of Primary Structures of Polar Class Ships

Ville et al. (2020) proposed a robust and simple-to-use assessment methodology and acceptance criteria. The proposed method provides means to ensure proper structural hierarchy. Appropriate

safety margins are described through the plastic response of the local frame and the primary structural member. Allowable plastic deformation caused by the design ice load is determined by relating the permanent set of the structure to newbuild vessel production tolerances. An example analysis comparing the proposed method to existing linear and nonlinear methods is presented. The proposed method ensures that the structure remains serviceable throughout the lifetime of the vessel and provides a tool to make the primary structures of polar class vessels lighter and safer by filling the gap of missing detailed acceptance criteria for nonlinear analysis in the PC rules.

Guidelines for Transverse Web Frame Design in Polar Class Ships

Edward (2018) presents guidance on how to develop accurate finite element models for polar class ships and provides guidance on appropriate acceptance criteria for the plastic design/behavior of transverse web frames. Some design considerations should be taken into account to ensure the design will be sufficient in accidental overload scenarios. Several geometric models were created to study how different design factors influence the response of the transverse structure. One of the models created was that of a PC3 icebreaking side shell structure. For most overload scenarios, the solver will require both material and geometric nonlinear capabilities. Depending on how the

load is modeled, an indenter may be used which requires nonlinear boundary capabilities in the form of contact.

A New Ice-Resistant Jacket Platform Based on Field Monitoring

Offshore structures in ice-covered waters are exposed to the actions of drifting ice floes. The ice sheets may push over a weak platform or generate significant loads on it. The loads affect not only the routine operation of an offshore platform such as drilling and production activities, but also the safety and serviceability of the structure. In order to reduce the dynamic ice load acting on the platform, the offshore structure's conventional design should be changed.

Firstly, the global ice load acting on structure can be reduced by reducing the number of legs exposed to ice action, and reducing diameter of legs to lower the projection area of ice excitation. On the other hand, the dynamic ice load acting on structure might be reduced by changing the failure mode of ice floes. Conventional steel jacket platforms always use cylinder leg at water level, and ice crushing failure on cylinder exerts the highest loads. Installing a conical component at water level is an effective solution to change the failure mode of ice from crushing to bending, and to reduce the magnitude of ice load significantly (Wang et al. 2012).

In order to make use of the research result, a newly designed platform, JZ20-2NW, was deployed in 2005. On this platform (Wang et al.

2012; see Fig. 7 below), new conceptual designs were used, including single-leg design and icebreaking cone constructed at water level.

Definition

Structural design refers to the creative work that transforms the design tasks and requirements of the structural system into technical documents that can be implemented. The designer needs to analyze, calculate, draw, and test all the components of the structural system according to the actual original conditions and finally present all the drawings for production and the relative technical documents. This process usually involves constant revisions to pursue perfection, which brings together the creativity and inventiveness of the designers (Yu 2010).

Scientific Fundamentals

The Main Contents of Structural Design

The contents of structural design can be summarized as follows (Yu 2010):

1. Structural layout design. The locations and deployment of components and equipments of the structural system should be proper and co-ordination.
2. Selection of structural shapes and arrangement of the bearing members. When subjected to working loads, the structures demand reasonable forms, which do not only have good mechanical properties to meet the requirements about strength and stiffness but are as light as possible.
3. Determining the sectional dimensions of the structures according to task assignments and the specifications.
4. The selection of structural materials. The material selection of marine engineering needs comprehensive considerations. Metal, composite materials and non-metallic materials are commonly used in marine structures, among which steel, titanium alloy, composites, and ceramics are most widely used.
5. The selection of components composing structural system and the ordering requirements, as well as corresponding technical requirements and standards are supposed to be decided in structural design.
6. The strength, stiffness of the structures, and corresponding tests. Structural strength and stiffness are the capability of structures to withstand external loads, namely, the ability to resist fracture, failure, and deformation or displacement. In addition to theoretical calculation, mechanical properties of structures must be verified through relevant tests.
7. Interface design. Interfaces include the connections between components, equipments in the structural system, and the connections among different systems. Interface design deals with a lot of coordination work throughout the whole process.
8. The design and layout of maintenance channels. Convenient repairments and efficient maintenances of the structures will be based on reasonable layouts of maintenance channels.
9. Forming a set of drawings that can be used to produce as well as all the technological files in the design process.

The overall project design encompasses conceptual design, preliminary design, technical design (detailed design), and construction design in successive order, and the emphases of structural design vary with different design stages (Yu 2010; Zhu 1992).

In conceptual design, a variety of structural design schemes are usually made, each of which will be analyzed to be compared according to design project description requests, and finally a reasonable design scheme is chosen after comprehensive considerations and assessments about feasibility and economy.

In the preliminary design, the structural design focuses on fully understanding and analyzing the original conditions such as the design tasks and the overall design data, analyzing the loads, service conditions, production conditions, determining the principal dimensions of the structures as well as various interface relations, the structural configuration, the arrangement of the bearing components, and completing the overall design drawing of the structures.

In the detailed design, main endeavor will be done in the following aspects. Carrying out

structural analyses of components, especially, fatigue, durability, and damage tolerance are also analyzed and accessed for the reused parts and components. During the design process, necessary tests should be carried out to check the properties of material or the performance of the structures. A complete set of engineering drawings for submitting and production, together with corresponding technical documents for this stage, should be completed.

Construction design combines the technical documents of detailed design and the production capacity of manufacturers to produce working drawings, craft equipments, documents about equipments acceptance, installation, and testing. Structural design is not always included in the construction design (Zhu 1992).

All the work above will be demonstrated and evaluated according to the timeline.

Original Conditions of Structural Design

It is a prerequisite for structural design to understand and analyze the original conditions sufficiently. The main contents of the original conditions are as follows (Yu 2010):

1. The structural design task descriptions and the data related to the overall requirements; the theoretical demands to the structures in the shape, size, properties, etc.; and the specifications and installation requirements of the payloads inside the structural system (if any).
2. The working environments of the structures. The working environments can range from storage, transportation, operation/service, to deployment or recycling environment, leading to various loads, to all of which the structures must be adapted.
3. The interface relations inside and outside of the structural system, which will pose restrictions and requirements on structures. The contours, dimensions, and weights of the structures should meet the requirements about the interface relations, space layout, and performance.
4. The production conditions of the manufacturers. In order to design structures better, the designer should know the production capacity and assembly equipments of manufacturers,

the technical level and processing experience of technicians and workers, and the possibility of adopting new materials and new technology.

5. The cost of the structures. The more complicated and higher performance of the structural system, the higher it costs. Structural design aims to achieve balance between economy, safety, reliability, and high performance.

Loading Analysis in Structural Design

Loading analysis is one of the main bases for structural design. There are various kinds of loads that affect marine structures, e.g., loads due to working environments (the wave induced loads, the hydrodynamic loads, the sloshing loads, the impact loads, and so on (Wang 2013)), gravity, loads during ground operation, loads during the launching and recovery period, etc.

The maximum working loads that a structure bears under normal service conditions is p_w , and the corresponding stress is σ_w . It is not allowed for structure that either any deformation impeding working in order under the service load or harmful residual deformation after unloading occurs. Therefore, the structural design should ensure that σ_w of the main structural components should not exceed the ratio limit of the material σ_p , that is (Zhang 2011),

$$\sigma_w \leq \sigma_p \quad (1)$$

The Calculation Load Method

The calculation load method is widely used in the actual structural design (Yu 2010). In which the calculation load is obtained by multiplying the load by the safety factor f ($f > 1.0$).

$$p_c = p_w f \quad (2)$$

And the strength criterion is:

$$p_u \geq p_c \text{ or } [\sigma] \geq \sigma_{c, \max} \quad (3)$$

Where p_u is the ultimate load of the structural material, $[\sigma]$ is the ultimate stress of a component, which can be the tensile stress σ_b or the critical stress σ_{cr} , depending on the load being

compression or tension. If $[\sigma]$ is not less than the maximum stress in the components under calculation load $\sigma_{c,max}$, the structure will be destroyed or lose the bearing capacity (Yu 2010).

The advantages of the calculation load method lie in two aspects. First, when adopting the calculation load method, the working stress of the structures are near the ratio limit of the material, and some components are allowed to work beyond the elastic range of the material, so the material can be fully used and the structures can be lighter. Second, it is convenient to observe the results of the tests and to compare the theoretical results with the test results (Yu 2010).

Safety Factor

The safety factor is associated with the calculation reliability, the materials, the manufacturing level, the maintenance, etc. The safety factor is greater than 1.0, providing safety margin in cases that the actual loads exceeding the service load and that the uncertainties in the materials and design procedure are inevitable. If the safety factor is too large, the structure system will be larger and its performance can be decreased. If it is the opposite situation, the structure may be too risky to fail during service. The safety factor should not be determined only to ensure that the structure has enough strength, stiffness, and stability, but the structure mass is not too large. The method for determining the safety factor is generally as follows (Yu 2010; Zhu 1992):

$$f = f_1 f_2 f_3 f_4 \cdot f_i \cdots \quad (4)$$

f_1 is the ratio of the strength limit to the proportion limit of material, in order that the structure does not have permanent deformation under the working load, and it is the main factor determining the safety factor.

f_2 is concerned with fatigue and permanent deformation of materials, and it is generally greater than 1 except for some disposable equipments.

f_3 mainly focuses on the influences of such errors as the calculation errors of the loads, the deviations of the material performances, the

errors of the assembly, and the errors of the measurements.

f_4 is presented to guarantee the safety of the ground crew.

And f_i is the i_{th} impact parameter to the safety factor. The factors in Eq. (4) are always greater than 1.0.

It is more feasible for the safety factor to be determined by probabilistic methods as the factors are all random. The standard safety factor is selected on the basis of a large number of data accumulations from various structures over decades.

Stress Analysis

The procedure of stress analysis is introduced in Bai (2003). Stress analysis plays an important part in structural design, predicting various behaviors of structures under service loads and working conditions. The different modes of failure are not likely to arise at the same time; in more cases, the failure occurs by one or two mechanisms. It is rather difficult to design a complicated structure of high performance merely using simple qualitative calculation, and thus the strength analysis is indispensable in structural design.

Nowadays, the major classification societies all over the world, such as ABS (ABS 2010), CCS (CCS 2013), LR (LR 1989), BV (BV 1989), DNV (DNV 1988), GL (GL 2009), RS (RS 2004), NK (NK), have provided evaluation, calculation methods, and other technical service associated for marine structures, which are one of the main kinds of business lines of the classification societies.

In the conventional strength analysis, there are always design calculation and checking calculation (Yu 2010). The design calculation is carried out in the earlier stage of structural design, and the purpose is to obtain the basic section sizes of the main force elements. The methods of design calculation should be simple and of certain accuracy. Theoretical formulas, empirical or semi-empirical formulas in elastic mechanics, structural mechanics, and material mechanics are often employed in design calculation methods, and analytical solutions might be obtained for simple structures.

The checking calculation is implemented after determining the structural details. The purpose of the calculation is to get the strength data of the whole structural system and each component to check the results of design calculation and to decide whether the design scheme need further modifying and optimizing (Yu 2010). Therefore, the accuracy of checking calculation is very important, and finite element method and non-linear analysis programmed and executed on computers are often used to get accurate results as far as possible. The finite element analysis (FEA) was proposed by Clough (1960), and its basic idea is dividing a continuous system into a finite number of elements, establishing the matrix equation about the displacement and force of every element, and seeking the solution to the matrix equation. FEA can be applied to complicated structures with irregular geometries and is easy to be programmed and executed utilizing computers, as a result, FEA has become an important approach to structural design in variety of industries.

Tests in Structural Design

It is insufficient to accurately analyze the structures merely depending on the theoretical calculation. The tests on the real structures are necessary to check the theoretical results and identify the actual structural strength.

There are many tests during the process from design to manufacturing and operation of the structures (Yu 2010). The tests can be categorized by different classification methods, e.g., static strength tests and fatigue strength tests due to different load style, ground tests and pressure cylinder tests due to different test places, component tests and structure tests due to different tested objects, the calculation load tests and the failure tests according to different loads, etc.

The History of Structural Design

The structural design develops in the wake of improvements of science and technology.

There was recording about human diving using equipments as early as in the fourth century B.C. (Zhu 1992), when the workers or artisans might rely on their life experience and intuition

to some degree rather than accurate calculations due to lack of science and technology.

Thanks to the development of mechanics and mathematics, analogy and empirical mathematical formulas were used in the calculations of structural design. The theoretical analysis methods of rods, plates, beams, trusses, shells can be found in material mechanics and structural mechanics, such as force method, displacement method, matrix displacement method, finite element method, and so on, which laid foundation for structural strength analysis (Yu 2010). The mechanics theory and abundant design practice combine to form empirical design or semi-empirical design by scientific summary and improvement, which is traditional approach to do structural design before and even after computer technology coming into being.

However, in most cases, it is unlikely to get the analytical solutions to the analysis of complex structures using theoretical methods. Thanks to the development of computer technology, revolutionary changes have been made to structural design, forming the modern design methods (Wang 2013). In modern design, system tools are used to implement the integrated design of man-machine-environment system, to make the concepts, process, and organization of design more reasonable and to optimize the process, strategy, scheme, and data selection of design (Yu 2010). The computer technology is universally used in calculation and drawing of large-scale structures, e.g., in the structural design of modern ships and offshore platforms, subbottom tunnels, whose structures are becoming larger and more complicated. Along with the concepts of reliability design, multi-objective optimal design and risk-based assessments of structures which are expensive and time costly being recognized as urgent; computer technology is playing a more and more key role in such design work because of their high efficiency and calculation capacity, saving a lot of time and money, until now there have been a number of commercial softwares which are widely used in marine engineering (Bai 2003).

The modern design methods can improve design quality and shorten the design cycle, as a

result, the efficiency is enhanced. In a manner of speaking, at present, the modern design methods are indispensable in the marine structural design.

Key Applications

Submersibles

Submersibles are important technical means for human beings to carry out deep-sea developments, see Fig. 1. They can carry various electronic devices, mechanical equipment, or even engineering technicians and scientists to reach ocean floor quickly and accurately, and conduct explorations, scientific investigations, and such work efficiently (Liu 2001). Generally, submersibles can be grouped into four kinds: human occupied vehicle (HOV), remotely operated vehicle (ROV), tethered mapping system (TMS), and

autonomous underwater vehicle (AUV). There into, New Alvin of USA, Mir I & MIRII of Russia, Nautilus of France, Shinkai6500 of Japan, and Jiaolong of China are the main operation type deep HOVs (Pan and Cui 2011), and unmanned submersibles that have reached the ocean floor in the Mariana Trench were Nereus of USA and Kaiko of Japan (Vaskov 2012). The structural system of a submersible includes pressure and non-pressure structures, and relative design methods are available in classification societies' rules. Among pressure structures, pressure vessels provide normal pressured and sealed space for equipments, apparatus, or personnel contented. The pressure vessels should be designed to be of sufficient structural strength, reliable sealing, and as light as possible. The pressure vessels are generally in the shape of cylinder, sphere, ellipsoid, or combination of shapes

Structural Design, Fig. 1 Various kinds of submersibles. (Pictured by CSSRC)

abovementioned (Liang et al. 2004). Most of the deep HOVs' manned cabins adopted the form of a single ball with multiple openings, and the strength and stability of such kind of hulls have been investigated since 1915 (Pan et al. 2012); Pan et al. have studied the ultimate strength of deep manned cabins (Pan et al. 2010, 2012; Pan and Cui 2011), and the cylindrical pressure structures are mostly used for submersibles no more than 800 m (Zhu 1992). Reliable sealing is another critical technology in pressure vessels design. Buoyancy material is also a kind of pressure structure, which provides buoyancy compensation for the submersibles. The structural design of buoyancy material needs to examine the pressure resistance performance, machinability, and water absorption properties of the material itself comprehensively. The appropriate design of buoyancy material can guarantee the buoyancy of the submersibles, increase the payload, improve the contour and size of the submersible (He et al. 2017). Ceramic matrix composites housing and buoyancy have been used in Nereus, obtaining excellent bulk density (McDonald 2014; Stachiw et al. 2006; Weston et al. 2005) which can provide positive buoyancy. The non-pressure structures which do not form closed vacuum are composed of light shells and frame mainly, and they provides a smooth shape, protecting enclosure, connection, and supporting of equipments for the submersible. The structural design is supposed to satisfy the requirements of the working environments and the task assignments, and consider the existing technological level such as processing, welding, heat treatment, composite technology of composites, and so on to control the structural deformation.

Ships and Offshore Platforms

Ships and offshore platforms are important marine structures and are of significance in social economy. The main material in the construction of the marine structures is steel, which accounts for the 20–30% of the construction cost of the engineering, and the steel products include steel plate, formed steel (marine bulb bar, H-steel, angle steel, cast steel and forged steel, welding materials, and accessories (Wang 2013)). Steel plates

are mainly used to make the ship hull, angle steel and formed steel are mainly used to make the hull structures; bulb bars are mainly used for making the hull keel, and steel pipes are mainly used to make the vessels on the ships. Because of the wide application of the steel, the steel weight is about 60% of the total ship weight. Offshore platforms are large welded, trussed constructions composed of all sorts of string bars and inclined rods. High performance marine steel products are demanded to have high strength, high toughness, good weldability, corrosion resistance, and crack arrest characteristics (Yang and Su 2012).

As the utility specialization of modern ships, there are various types of ships, e.g., oil tankers, bulk carriers, container ships, et al., the scantling of which may be different from each other. With the development of marine oil and gas resources, offshore platforms are being built from shallow sea to deep sea gradually. The three motion modes offshore platforms and the main subtypes are demonstrated in Fig. 2 (Di et al. 2008), and structural forms are different more or less with types.

As for marine structures withstand very harsh working conditions, including a variety of climate conditions, wind and wave invasion, and seawater corrosion, therefore brittle fracture and fatigue damage of the structures are to be prevented, special attention should be paid to strength calculation and checking, fatigue resistance and corrosion resistance in structural design. Global or local stress analysis can be conducted using computer technologies besides the conventional methods, leading to the development of many sophisticated commercial softwares.

Welding is basic technology in such large scaled and complicated steel structures as modern ships and offshore platforms, and the technical requirements of welding are becoming higher. Due to local heating and the following uneven heat in welding, residual stress is easy to occur in welded joint areas, which makes welding parts particularly vulnerable to defects. The weld joints are more sensitive to fatigue loads, and issues such as welding materials, welding methods, welding technology, and welding inspections can all affect the structural performance; hence, the welding defects are usually reduced by

Structural Design,**Fig. 2** Different types of offshore platforms. (Drawn according to Di et al. 2008)

controlling the welding process, through selecting suitable welding material (with properties matching the parent material), preheating before welding, and heat treatment post welding (Yu 1992). In addition to the design calculation and analyses, the welding procedure is formulated, in which the rules and requirements are clearly specified so as to ensure the strength and fatigue resistance of the platform structures.

Definition

Submarine is the general name of all kinds of underwater vessels. Submarine is a kind of naval vessel that can sail and fight on the water and at a certain depth under water.

Scientific Fundamentals

Composition and Basic Type

System Composition

The submarine is mainly composed of hulls, control systems, power units, weapons systems, observation equipment, communications equipment, and navigation equipment. The equipment on board is mainly divided into five parts according to functions: observation system, communication system, navigation system, weapon system, and electromechanical system. Submarines usually use the following four types of shapes: conventional one, water-drop one, like water-drop, whale-shaped (Zhong and You 2017).

The weapon cabin includes torpedo cabin and missile cabin. Torpedo cabin of the modern submarine is generally located in the stern and used to store and launch torpedoes, missiles, and mines.

The missile cabin is located in the middle of the submarine and used to store and launch cruise missiles and ballistic missiles. The power cabin is the heart of the submarine, which is commonly close to the submarine raft and equipped with the main and auxiliary power machinery. The command cabin is the operational center of the submarine, which is located below the submarine's bridge. It has some system equipment for manipulation, observation, detection, and control. The living cabin is the place where the crew rest. It includes crew's rooms, the dining room, the conference room, and other security cabins. The lower floor of the living cabin is generally equipped with the battery, which is called the battery cabin (Zhong and You 2017).

Submarine Types

The submarine can be divided into four categories according to the displacement size: the large submarine, the medium submarine, the small submarine, and the pocket submarine (Xie 2007).

The displacement exceeding 2000 t is the large submarine, as shown in Fig. 1. This kind of submarine has greater self-sustaining power, endurance, and a large amount of weapons and equipment. On January 10, 2013, the first “Borei-class” strategic nuclear submarine named “Yury Dolgorukiy” was officially served. The submarine is defined as the medium one for the displacement between 600 t and 2000 t, which has less self-sustaining power, endurance, weapons, and

equipment than the large submarine. However, the medium submarine is more flexible and can execute the tasks in the middle sea. This submarine currently occupies a considerable proportion of conventional submarine in various countries. The displacement between 50 t and 600 t is the small submarine, which is suitable for offshore and shallow water areas. And its self-sustaining power, endurance, weapons, and equipment are all relatively small. Nevertheless, the small submarine has high flexibility and low cost advantages. Meanwhile it is convenient for mass production in wartime. The displacement below 50 t is the pocket submarine, which is used to raid the enemy's base and conduct reconnaissance activities. And the pocket submarine is usually transported by other submarines, surface ships, and helicopters, then moves by its own (Xie 2007).

The submarine is divided into open sea submarine, near sea submarine, and offshore submarine according to the navigation area. Meanwhile, this division is usually commensurate with the size of the displacement. So the open sea submarine usually refers to the large submarine, the near sea submarine refers to the medium submarine, and offshore submarine refers to the small submarine. The submarine is also divided into the attack submarine, anti-submarine, radar warning submarine, minefield submarine, and the transport submarine according to the missions (Wolfpack 2010).

Development History

The development of submarine can be traced back to the Renaissance in Europe. The first person to

Submarine, Fig. 1

Russian “Borei class”
ballistic missile submarine
trimmed on the surface
(Yu 2013)

design submarine was Da Vinci, the Italian artist. The first documented submarine researcher was an Italian, named Leonard, who proposed the theory of underwater hull structure in 1500 AD. In 1578, William Bourne, a British navy lieutenant, recorded his research on the submarine theory in his book “Inventions.” In 1620, Cornelis Drebbel, a Dutch physicist, built the first diving boat in human history (Tierie 1932), so he was called “the father of the submarine.”

The first military submarine appeared in the American Revolutionary War. David Bushnell from Yale College (now known as Yale University) built the “Turtle” (shown in Fig. 2). Only one person was allowed to operate the rudder and the propeller due to limited inner space. The “Turtle” could dive to the depth of 6 m and stay for about 30 min through the foot valve to the water tank. (Zhong and You 2017).

The early submarine was all human powered and its speed was very low. In 1863, the “Plongeur” built by French was powered by a steam engine with 59 kW (80 hp). Its speed was 2.4 knots. It was able to submerge underwater for 3 h at the depth of 12 m. In 1886, the “Nautilus” built by British was powered by the battery and had a speed of 6 knots with an endurance of about

80 nautical miles. In 1880s, the United States, Britain, France, Sweden, Italy, Germany, and Russia began to study and develop new types of the submarine. It was not until 1900 that the navy of the United States began to equip the submarine (Donitz 1958).

In the late 1880s, the development of the submarine attracted the interests of more countries. In 1893, the “Gustav Zede” with a length of 45.7 m and a displacement of 266 t was launched in France. It was powered by the motor propellers. At that time, it was the most advanced one in the world (Bowers 1999).

At the end of nineteenth century, an American youth Simon Lake got the inspiration from the science fiction “20,000 Leagues under the Sea” and built the “Argonaut” based on its own power. The submarine sailed from Norfolk to New York, so it became the first one on a long voyage in human history (John and David 1986).

At the beginning of twentieth century, the equipment and performance of submarine were gradually improved with certain actual combat capabilities. The submarine with double shells was powered by the dual-propulsion and diesel-motor system. It had a displacement of several hundred tons and good seaworthiness. The endurance of it was significantly improved (Parker 2007).

At the beginning of the World War I, the submarine quickly became a new star on the sea battlefield. The number of submarine in various countries is shown in Table 1. In 1914, the “German U-9” (shown in Fig. 3) sank three British 10,000 t cruisers at the slight cost of six torpedoes in just over an hour, which strongly verified the

Submarine, Fig. 2 The diagram of the internal structure of the “Turtle” (Zhong and You 2017)

Submarine, Table 1 The number of submarines in major countries on the eve of the World War I in 1914 (Zhong and You 2017)

Nation	In service	In the construction
Britain	77	32
France	45	25
America	35	6
Germany	28	13
Russia	28	2
Italy	18	2
Japan	13	2

(Williams 2008)

submarine's combat effectiveness (Douglas 1999).

After the World War I, the major naval countries paid more attention to the construction and development of the submarine. The submarine not only acted as the defensive force, but also was assigned to various offensive tasks. The number and type of the submarine were increasing, some had more than 2000 t of displacement, 100–200 m of diving depth, 7–10 knots of underwater speed, 16–20 knots of surface speed, more than 10,000 nm of endurance, 1 or 2 months of self-sufficiency, 6–10 torpedo tubes, more than 20 torpedoes, and 1–2 guns. In the later part of the war, the submarine was equipped with radar, radar reconnaissance instruments, and self-guided torpedoes (Delgado 2006).

After the World War II, the navies of various countries in the world began to attach importance to the development of the new submarine. The use of nuclear power and strategic missiles brought the development of the submarine to a new stage. In 1955, "Nautilus," the world's first nuclear-powered submarine built by the United States (shown in Fig. 4) was in service. Its underwater speed and the time of endurance increased (Preston 2009). The emergence of ballistic missile nuclear submarines caused a fundamental change in the role of submarines. It had become a strategic nuclear strike force under the water (The Submarine Turtle 2008).

After 1980s, new conventional submarine was designed and built by Soviet (Russia), Germany, Sweden, the Netherlands, Japan, and other countries. The new Air Independent Propulsion submarine without air propulsion was developed quickly, such as the Russian "Lada-class," Germany's "212-class" and "Export 214-class," Sweden's "Gotland-class," Japan's "Soryu-class". It had gradually become outstanding representatives and development trend of nonnuclear-powered submarine in the world (Zhong and You 2017).

Key Technology

The power equipment used by the conventional powered submarine is the diesel-electric power equipment and the Air Independent Propulsion (AIP) equipment (Yu 2013).

The diesel-electric power unit is the earliest and most widely used in the development history. It is mainly composed of a diesel engine, a battery, and a main motor. Fig. 5 shows a conventional submarine using a diesel-electric power unit. The diesel engine is the main power unit of a conventional submarine for the surface navigation with the speed of 10–15 knots. The main motor is the main power unit of a conventional submarine for underwater navigation with the speed of 15–20 knots driven by the battery. The diesel-electric power unit is also equipped with economical

Submarine, Fig. 4

“Nautilus,” the world’s first nuclear powered submarine (Yan 2012)

**Submarine, Fig. 5**

German “206” conventional submarine uses diesel-electric power unit (<http://www.baidu.com/>)

electric motors as an auxiliary power with the underwater speed of 2–4 knots. However, due to the limitation of the battery power, the submarine needs to float to the snorkel for a period of time and use the diesel generator to set up battery for charging. At this time, the submarine is easily discovered and attacked. For this problem, the Air Independent Propulsion (AIP) came into being. The AIP was originally developed in Sweden and used the oxygen carried by the submarine to complete the conversion of energy, which

provided the propulsion power for submarine under the water. Comparing with ordinary conventional submarines, the devices equipped with AIP could stay underwater for at least a week. In addition, the AIP is more secluded. The operational effectiveness of the AIP is already close to nuclear submarines (Yu 2013). In most countries, the navy is unable to purchase nuclear submarines because of military spending and restrictions on combat waters, so the AIP is a good choice for them.

The nuclear-powered submarine emerged due to the great advantages of the nuclear power. And the power system of the nuclear powered submarine is composed of nuclear reactors, steam generators, pressurizers, main circulation pumps, and main steam turbines. Utilizing the nuclear power as driving force, the power of submarine has undergone a fundamental transformation. It could reach tens or hundreds of megawatts and continuously work for many years with one loading. Its endurance can reach hundreds of thousands of sea miles or even greater. Because the nuclear power unit does not rely on the air, the submarine can sail underwater for a long time and has good concealment, which has become one of the most important strategic weapon platforms in the new era. Nuclear power unit is usually used as the main power unit for nuclear submarine. Nuclear submarine is also installed auxiliary power devices, such as diesel generator sets, power storage units, and electric motors, which provide emergency power for nuclear submarines when needed (Ross 2012).

The submarine is usually equipped with a variety of weapons. At present, the submarine's weapon system mainly includes various missiles, torpedoes, and mines. Missiles are the main combat weapons of modern submarine including ballistic missiles, cruise missiles, anti-ship missiles, anti-submarine missiles, etc. The submarine carries different missiles for the different tasks. Torpedo is a traditional submarine weapon and used to attack and counter attack against boats. Strategic nuclear submarine uses intercontinental ballistic missiles as weapons. Attack nuclear submarine uses various cruise missiles and anti-submarine missiles as weapons. For the strategic nuclear submarine, the ballistic missile carried by the submarine has the range of 10,000 km and the missile can carry the nuclear warhead. So the strategic nuclear submarine is the symbol of national deterrence. So far, only the United States, Russia, Britain, France, and China have strategic nuclear submarine in the world, such as American "Ohio-class" strategic nuclear submarine, Russian "Typhoon-class" strategic nuclear submarine, French "Triomphant-class" strategic nuclear submarine, British "Vanguard-class" strategic nuclear

submarine, and Chinese "Type 094" strategic nuclear submarine. For the attack nuclear submarine, the main task of it is to search information and attack the enemy submarine, aircraft carrier combat groups, and surface warship formations, so that the strategic missile submarine, aircraft carrier combat groups, or marine mobile formations, as well as strategic campaign reconnaissance, have the safe channel. Meanwhile, the attack nuclear submarine can conduct the maritime escort and destroy the enemy traffic lines. Attack nuclear submarine and strategic missile submarine are mainly distributed in the United States, Russia, Britain, France, and China. The United States is the first country to develop attack nuclear submarine. The latest US attack nuclear submarine is the "Virginia-class" nuclear submarine. The fourth generation of Russian attack submarine is the "Type 885 Severodvinsk." The newest British nuclear submarine is the "Astute-class" attack nuclear powered one, which uses advanced floating raft damping technology. French newest attack nuclear submarine is "Amethyste-class," which is produced to meet the new operational needs of the French navy. The Chinese attack submarine is the "Type 091" and "Type 093" (Zhang 2014).

The pressure-resistant hull structure is designed to withstand the high water pressure in the deep sea for the submarine. Meanwhile, the submarine needs to wrap all or part of it with a nonpressure hull structure. Therefore, the submarine must have a smooth surface to reduce the resistance. The hull structure of modern submarine can be divided into four types: the single-shell submarine, the half-shell submarine, the double-shell submarine, and the single-double-mixed shell submarine, depending on the degree of wrapping. The single-shell submarine has only one layer of pressure-resistant shell. The main ballast tank is arranged in the pressure hull. And the submarine has less water flow holes at the outer surface, good smoothness of the hull, small wet surface area, low resistance encountered during underwater navigation, and rapid submersible speed (Yu 2013). The single-shell structures are mainly used in European and American, such as the United States "Sea wolf class SSN" attack

nuclear submarine, the British “Trafalgar-class SSN” attack nuclear submarine, the French “Rubis class” attack submarines, German “209” and “214,” and Swedish “Gotland” conventional submarines. The half-shell submarine has a layer of coating around the pressure hull as the half shell, which is a double shell area with pressure and nonpressure tanks. The bottom of the pressure hull is still exposed to the outside. Compared with the single-shell structure, the internal space and external line pattern of the half shell are improved. From the development history, the submarine with half shell structure is less. The submarine with the inner shell and the outer shell is the double-shell submarine. The inner shell is a pressure hull made of high-strength steel or alloy material, which is all wrapped by nonpressure outer shell. The main ballast water tanks, fuel tanks, fuel ballast tanks, and buoyancy control tanks of the submarines are located between the two shells (Yu 2013). The “Typhoon-class” strategic nuclear submarine with “Type 941” (shown in Fig. 6) is the largest ballistic missile submarine of the Russian navy. It is also the world’s largest volume and tonnage submarine record holder up to 2017.

The double-shell structures are used in the former Soviet Union, Russia, China, and Japan. The typical double-shell submarine is the “Oscar-class” and “Typhoon-class” nuclear submarine. The single-double-mixed shell submarine appeared in 1950s. It can reduce the displacement of submarine and the wet surface area of the hull, and increase the underwater speed and the ability

to fight at critical locations. With the rapid development of technology, the design of the shell structure has become more and more mature. Instead of the traditional single-shell and double-shell structure, the mixed-shell gradually becomes the mainstream (Yu 2013).

Key Applications

In the twenty-first century, with the continuous development of economy and the advancement of technology, the development of the submarine in various countries was in boom times, the development of submarine had created a wave of competition in quantity and quality all over the world.

On November 9, 2012, the “Tourville,” which was the first pressure-resistant shell section and the third French “Barracuda-class” attack nuclear submarine, was built by the “DCNS.” Meanwhile, there would be six “Barracuda-class” nuclear submarines to be delivered to the French Navy from 2017 to 2027, and they would replace the current four “Rubis class” nuclear submarines and two modified “Amethyste class” nuclear submarines.

Russian submarine, at the beginning of 2012, the Russian Ministry of Defence decided to sequentially build 13 “Oscar class” nuclear submarines (shown in Fig. 7) and update the existing ones.

At present, the Russian navy has equipped 27 nonstrategic attack nuclear submarines, 9 guided missile submarines, and 18 multipurpose nuclear submarines. Among the guided missile

Submarine, Fig. 6 The “Typhoon-class” ballistic missile submarine is the largest submarine in the world (Yu 2013)

Submarine, Fig. 8 Chinese submarine (<http://www.baidu.com/>)

submarines, there are eight “Oscar II” submarines and only one “Type 885 Yasen class” submarine named “Severodvinsk.” Among the multipurpose nuclear submarines, there are 11 “Akula-class” submarines with “Type 971,” 2 “Sierra Class I” submarines, 2 “Sierra Class II” submarines, and 3 “Victor-class” multipurpose nuclear submarines. “Ohio-class” nuclear power submarine has a length of 171 m, a width of 13 m, and a displacement of 18,750 t. The submarine has been in service for 30 years.

The British Navy will own 4 “Vanguard-class” strategic missile submarines and

7 “Astute-class” attack nuclear submarines, which have been planned to extend the life to around 2028. At the same time, the Trident missile’s “Vanguard-class” in service will be replaced by the new generation of nuclear submarines, which is scheduled to serve the navy in 2028 (Zhong and You 2017).

For China, there are two kinds of submarines: the attack conventional power submarine and the nuclear power submarine. And the total number of submarines built is over 130. The “Ming-class” (Type 035) and “Song-class” (Type 039) submarines are the attack conventional power ones. The

Submarine, Fig. 9 “Columbia-class” nuclear power submarine. (http://en.wikipedia.org/wiki/Main_Page)

“Ming-class” (Type 035) is the first generation of conventional submarine. The “Song-class” (Type 039) is the second generation of conventional submarine and it achieves launching an anti-ship missile from a distance underwater firstly (Fig. 8).

The “Han-class,” “Xia-class,” “Shang-class,” and “Jin-class” submarines are the nuclear power ones. The “Han-class” (Type 091) is the first generation of attack nuclear power submarines in China. The “Xia-class” (Type 092) is the first generation of ballistic missile nuclear power submarine. And the “Shang-class” (Type 093) is the second generation of attack nuclear power submarines designed and built by China, entering service in 2006, which has the fast underwater speed, good concealment, and a powerful blow. Meanwhile, the “Jin-class” (Type 094) is the second generation of the ballistic missile nuclear power submarine, which has the largest displacement in Chinese submarine and is improved greatly in concealment, sensor, and propulsion system reliability.

The US Navy decided to convert the SSGN-726, the SSGN-727, the SSGN-728, and the SSGN-729 into a cruise missile nuclear submarine carrying conventional guided missiles. The “Columbia-class SSBN,” (shown in Fig. 9) the fifth generation of the United States ballistic missile nuclear submarine, is used to replace the

Submarine, Fig. 10 “Ohio-class” nuclear power submarine. (<http://image.baidu.com/>)

“Ohio-class” nuclear power submarine (shown in Fig. 10). This submarine with a length of 171 m, a width of 13 m, and a displacement of 20,810 t will be the largest submarine built by the US Navy. The research process of this submarine is quite smooth. It was formally approved in January 2017. And the submarine construction is

Submarine, Fig. 11 “Virginia-class SSN” nuclear power attack submarine. (<http://image.baidu.com/>)

planned to start in 2021 and scheduled to come into service in 2031. The “Virginia-class” SSN submarine (shown in Fig. 11) is the nuclear powered fast attack one of the United States Navy. Considering the time in service and the standard of construction of the American nuclear powered attack submarine, it is the seventh generation. But from the perspective of the technical features and the purpose, it belongs to the fourth generation.

This submarine with multipurpose tasks is used to replace large numbers of “Los Angeles-class SSN” in service. The “Los Angeles-class SSN” has a full length of 110 m, a width of 10 m, a full-load displacement of 6927 t. Its speed is 32 knots. The “Virginia-class SSN” with anti-submarine capability has gradually become the main force for the naval warfare in twenty-first century.

Definition

A *submersible* is a small vehicle designed to operate underwater. The term *submersible* is often used to differentiate from other underwater vehicles known as submarines, in that a submarine is a fully autonomous craft, capable of renewing its own power and breathing air, whereas a

submersible is usually supported by a surface vessel, platform, shore team, or sometimes a larger submarine. In common usage by the general public, however, the word *submarine* may be used to describe a craft that is by the technical definition actually a submersible (<https://en.wikipedia.org/wiki/Submersible>).

Scientific Fundamentals

Submersible Types

There are many types of submersibles, including both manned and unmanned vehicles. A division of various submersibles is given in Fig. 1. These include autonomous underwater vehicles (AUVs), remotely operated vehicles (ROVs), autonomous and remotely operated vehicles (ARV) or hybrid of ROV and AUV (HROV), glider, deep tow system (DTS), lander, float, human occupied vehicles (HOVs), atmospheric diving suit (ADS), deep submergence rescue vehicle (DSRV), and rescue bell. The detailed introduction to these various types of submersibles will be given in each entry of this encyclopedia, and in this entry, only the information about the general concept of submersible is given. Submersibles have many uses worldwide, such as oceanography, underwater archaeology, ocean exploration,

Submersible, Fig. 1 A division of various submersibles

adventure, equipment testing, maintenance and recovery, and underwater videography. Various underwater submersibles are the main working force for the research fleet. The users of these vehicles include offshore petroleum, telephone cable maintenance, science, surveying, salvage, and military.

Historical Development

Human curiosity for the natural world and human exploitation of ocean resources are the leading two factors for the progress of deep ocean exploration. People have dived into the sea to collect pearls from pearl oysters since very ancient times, but the depths of the oceans were beginning to be known only in the nineteenth century. The British survey ship *Challenger II* surveyed the Mariana Trench near Guam in 1951 and identified the deepest known point in the ocean at 10,912 m. This was named the Challenger Deep. However, as technology improves in accuracy and precision, the actual depth value for the Challenger Deep may vary. In the middle of the nineteenth century, British biologist, Edward Forbes, made the infamous statement that life did not exist at depths greater than 600 m. However, this statement was soon found to be wrong, and it inspired scientists to explore the oceans deeper and deeper. The existence of life in the deep sea was established in the late 1860s (MTS 2009).

Many early ideas in these two directions about the deepest ocean depth and deepest depth for life existence led primarily to the development of the human occupied vehicles (HOVs). Forman and Kohnen presented the early developments from the 1930s to 1960s and the later results from the 1960s to 2000s, respectively, of human exploration of the deep seas (MTS 2009). In the 1930s, William Beebe (1877–1962) and Otis Barton (1899–1992) initiated manned deep-sea exploration using a very small steel sphere named Bathysphere dangled in the ocean by a cable. It was the beginning of the modern era of humans entering the deep abyss in a pressure-resistant hull.

Manned observations using the Bathysphere in the deep sea rewarded the researchers with views of live marine life. However, it cannot dive to a

very deep depth due to the self-weight of the cable. Auguste Piccard (1884–1962) was the first to design a submersible without the use of steel cables. In 1952, he began building the famous bathyscaph *Trieste*. In 1958, *Trieste* was purchased by the Office of Naval Research (ONR) of the USA, and plans for Project Nekton started. The main purpose of Project Nekton was to reach the bottom of the Challenger Deep. On January 23, 1960, the bathyscaph *Trieste*, piloted by Jacques Piccard and Don Walsh, made one successful dive to the depth of 10,913 m of the Challenger Deep. However, in considerations of the length of day, sea state, and stirred cloud of sediment, *Trieste* stayed at the bottom for only 20 min. No photographs of the sea floor were taken (Piccard and Dietz 1961).

During the same period, the French navy also took great interest in building a deep manned submersible. The objective of *Archimede* was to reach 11,000 m. By 1959, construction and engineering work on *Archimede* were fully engaged. The scientific history of *Archimede* was summarized by Alan Jamieson who suggested that the reports from *Archimede* were far more valuable at the time than was realized (Jamieson 2015). However, in its whole life, it did not fulfill its original mission to reach the Challenger Deep.

Both the *Trieste* and *Archimede* submersibles are regarded as the first generation of deep submersibles to distinguish the other operational deep manned submersibles (MSs) such as Alvin of the USA (4500 m), Nautilie of France (6000 m), MIR 1 and MIR 2 of Russia (6000 m), Shinkai 6500 of Japan (6500 m), and Jiaolong of China (7000 m) (Cui 2013). The main goal in the 1950s for most deep dives was to set record depths, whereas in the 1960s, after reaching the Challenger Deep in the Mariana Trench, the development of manned submersibles focused more on the solution of certain practical and scientific problems. Now, the development of a second-generation manned submersible for full ocean depth (FOD) is the current challenge.

In the same process for some people diving deeper and deeper, other people started to explore the unmanned submersible called remotely operated vehicle (ROV). It was hard to define exactly who to credit with developing the first ROV;

however, there are two who deserve credit. The PUV (Programmed Underwater Vehicle) was a torpedo developed by Luppis-Whitehead Automobile in Austria in 1864, while the first tethered ROV, named POODLE, was developed by Dimitri Rebikoff in 1953 (http://www.rov.org/rov_history.cfm). The US Navy is also credited with advancing the technology to an operational state in its quest to develop robots to recover underwater ordnance lost during at-sea tests. They have funded most of the early ROV technology development in the 1960s into what was then named a “Cable-Controlled Underwater Recovery Vehicle” (CURV). This created the capability to perform deep-sea rescue operation and recover objects from the ocean floor, such as a nuclear bomb lost in the Mediterranean Sea after the 1966 Palomares B-52 crash and then saved the pilots of a sunken submersible off Cork, Ireland, the *Pisces* in 1973, with only minutes of air remaining. The next step in advancing the ROV technology was performed by commercial firms that saw the future in ROV support of offshore oil operations. Building on this technology base, the offshore oil and gas industry created the working class ROVs to assist in the development of offshore oil fields. Two of the first ROVs developed for offshore work were the RCV-225 and the RCV-150 developed by HydroProducts in the USA. Many other firms developed a similar line of small inspection vehicles (Christ and Wernli 2014). More than a decade after they were first introduced, ROVs became essential in the 1980s when much of the new offshore development exceeded the reach of human divers. Since then, technological development in the ROV industry has accelerated, and today ROVs are performing numerous tasks in many fields. Their tasks range from simple inspection of subsea structures, pipelines, and platforms to connecting pipelines and placing underwater manifolds. They are used extensively both in the initial construction of a subsea development and the subsequent repair and maintenance. With ROVs working as deep as 11,000 m in support of ocean exploration and research (Takagawa 1995), the technology has reached a level of cost-effectiveness that allows organizations from police departments to academic institutions to

operate vehicles that range from small inspection vehicles to deep ocean research systems (Teague et al. 2018).

Due to the cable restriction to the submersible movement, people in the 1980s started to explore the concept of an untethered remotely operated vehicle (UROV) (Griffiths 2012). This was the beginning of the development of autonomous underwater vehicle (AUV). Gwyn Griffiths (2012) provided a good account of the historical development process of AUVs, while Wynn et al. (2014) provided a good introduction about the current technology status and applications in marine geoscience.

Since the 1990s, many other new concepts of hybrid unmanned submersibles (Bowen et al. 2009), gliders (Rudnick 2015), and floats (Richardson and John 2001) were proposed and received fast development.

Key Technology in the Development of a Submersible

In the development of the various submersibles shown in Fig. 1, the most challenging equipment is the development of the FOD HOV since almost all of the technological challenges encountered in the development of unmanned submersibles are covered by the HOV.

In order to develop a more capable HOV for ocean scientists, in 1999, the deep submergence scientific community responded to a questionnaire circulated by Woods Hole Oceanographic Institution (WHOI) on improved submersible capabilities. Based on these results, WHOI developed some preliminary specifications for an improved HOV (NRC 2004):

- Increased depth capability
- Increased ascent or descent rates in order to reduce the transit time
- Increased visibility
- Increased sphere volume for personnel comfort
- Increased external science payload
- Increased battery capacity
- Automated position keeping in all axes
- Enhanced controls and monitoring for single-pilot control
- Pan and tilt video for each observer

By considering these requirements and current available technology, various persons (MTS 2009; Cui et al. 2014) have carried out a preliminary concept design of the FOD HOV, and the following key technologies have been identified.

The whole manned submersible may be divided into seven subsystems (Cui et al. 2014), and they are (1) the overall performance and general arrangement, (2) structural subsystem, (3) mechanical subsystem, (4) electric subsystem, (5) control subsystem, (6) acoustic subsystem, and (7) life-support subsystem. The technical problems to be solved for each subsystem in the development process are briefly introduced here.

The overall performance and general arrangement subsystem includes the hydrodynamic performance, general arrangement, and outfitting. In order to have at least 4–6 h bottom working time, descent and ascent times ideally need to be kept to 1–2 h (MTS 2009). Hence, the vertical descent speed needs to be about 1.5–3 m/s; however, this speed is almost an order of magnitude higher than that of a second-generation HOV. Therefore, the hydrodynamic performance has become a key technology to be solved in the development of the FOD HOV. Conceptually speaking, there are several means to increase the speed; hydrodynamical shape optimization; powered driving, flying, or gliding principle; resistance reduction by bubble generation or super-cavitation technique; or a mix of these.

The structural subsystem includes the manned cabin, small pressure spheres and cylinders, main framework, buoyancy material, composite light shells, and stabilized fins. In this subsystem, the most challenging problem is the design and manufacture of the manned cabin (Cui et al. 2015). If the traditional three-person sphere with an internal diameter of 2.1 m is designed, the required wall thickness would be 118 mm if the traditional titanium alloy Ti-6Al-4V ELI is used and this is too thick to be manufactured. Thus, higher-strength titanium alloy of 1100 MPa class or steel such as the maraging nickel steel of 1700 MPa class should be used. Now people are also exploring the use of high-strength glass or composite material (MTS 2009) for the manned cabin.

In order to be competitive against future unmanned systems with cameras evolving fast, the currently used viewports in the manned cabin are a limitation for transparency. Full-view, hemispherical, clear glass domes would be the ideal solution for transparency. Deepsearch explored the feasibility of a full glass personnel sphere, melding two areas of innovation (new material and large viewports) into one big undertaking (MTS 2009). Glass has been proven to withstand great ocean depths as evidenced by the widely used Benthos spheres and newer Vitrovex spheres. The virtues of unimpeded views are well recognized in shallower depth manned submersibles. Deep Rover, DR1002, Johnson Sea Link, SeaMagine, Deep-See, and others have proven the concept with acrylic spheres. However, due to its brittle nature, technical problems such as ease of manufacture, composition and coatings, testing protocols, hatch and penetrators, reliability, mounting in a frame, and even testing and safety need to be carefully studied. Scale model spheres should be fabricated. Pressure tests will determine seal interactions at the glass interface. Cycle testing of the scale models will be undertaken in a pressure chamber to $FOD \times 1.25$. Strategies for sphere retention will be tested as well for shock loading protection, practical serviceability, and human factors (MTS 2009).

Buoyancy material is another important structural system in a deep-sea manned submersible. Through the preliminary analysis (Cui et al. 2018), it is thought that the current solid buoyancy material of glass microballoon/epoxy resin can be optimized to the maximum collapse strength. This requires that one needs to use the buoyancy material exceeding the rule requirement in the full ocean depth manned submersible. One of the safety measures used by this exceeding the rule requirement is to shorten the life span. Yet how to determine the life of the buoyancy material scientifically and reasonably is a key question to be answered. What kind of testing methods and testing standards should be used to determine whether the buoyancy blocks in a submersible need to be replaced or continue to be used? One still needs to have an in-depth understanding of the

characteristics of buoyancy material's water absorption property.

Syntactic foam can be used but at a size and weight penalty for the design. In order to have lighter buoyancy material, one can use ceramic spheres, which have been applied in the unmanned FOD submersible *Nereus* (Bowen et al. 2009). However, one needs to solve the sympathetic failure problem (MTS 2009). The loss of the *Nereus* in May 9, 2014, further implied the significance of this issue.

The mechanical subsystem includes the main ballast water tank, the adjustable ballast system, the trim adjustment system, the propulsion system, the hydraulic system, the sampling system, the underwater emergency jettisoning system, and the emergency rescue buoy. For this subsystem, only if one wants to use a high pressure sea water pump, will there be some technology challenge in the development. However, one can use other options to realize the buoyancy adjustment function.

The electric subsystem includes electric power system such as batteries, electric power distribution system, lighting, video system, and VHF communication. The safe application of the lithium ion battery which has been used in *Shinkai6500* should be explored for the FOD HOV. The main concern is surrounded with handling, packing, charging protocols, and testing in oil-filled housings.

Observations and documentation of observations are key to the HOV capabilities required by the scientific community. The latest illumination is to apply all the lights with LED arrays which can provide twice the amount of illumination currently available from the HMI lights and also improve the beam pattern and uniformity of the illumination field. The internal video infrastructure is the foundation for present and future upgrades to imaging system components. The internal video system accommodates all external camera signals and internal computer displays and distributes them to recorders, monitors, and data overlay subsystems. The implementation of 3D HD video cameras would be an interesting option. It uses the submersible's master timing controller to synchronize cameras and lights as necessary. It includes:

- Camera command and control system: Controls all external camera and lens functions, and provides pan and tilt, zoom, and focus control. It also provides acquisition of still images or frame-grabs.
- Video routing system: The router interfaces the camera, recorder, and computer display source feeds to the monitors and recording devices in the personnel sphere.
- Recording systems: In-hull HDTV recorders with time code and auxiliary data input capabilities.
- Monitoring and display system: Consists of the displays used by the pilot and observers when controlling the external cameras.
- Synchronization and time code generation system: Provides synchronization and time signals as necessary to all imaging hardware in the personnel sphere as well as the external cameras and lighting system.

The command and control subsystem is that part of the submersible that allows the pilot (and potentially the observers) to interact with and control components external to the personnel sphere, as well as components that require integration of multiple inputs and outputs. Other tasks of the command and control system are to automate repetitive tasks and to provide assistance to the pilots and observers in safely accomplishing their tasks. For example, dive activities are simplified through automated heading, altitude, depth, and position-keeping capabilities, which will be particularly helpful during manipulation activities. In addition, it will provide more flexibility in interfacing with instruments both carried by the submersible and installed on the seafloor, as well as greater bandwidth for scientific data collection and logging. So the subsystem includes the navigational control system, the equipment control system, the information display and control system, the navigation and positioning system, and the surface monitoring system.

The acoustic subsystem includes an underwater acoustic communicator, the underwater acoustic telephone, the acoustic positioning system, high-resolution side-scan sonar, acoustic Doppler velocity log, anti-collision sonar, imaging sonar,

long-distance ultrashort baseline positioning sonar, and long baseline positioning sonar. The acoustic equipment can be ordered from commercial companies.

Until recently, live transmission from HOVs at depth was limited chiefly to through-water acoustics with a bandwidth too narrow for anything but voice and position data, and low-resolution frame grab images. The principal problem with acoustic transmission to the surface is stratification of the water column. One solution is to transmit to an acoustic receiver (modem) at depth that is connected by wire or optical fiber to the surface. Even more promising is the use of an optical fiber that links the HOV to the surface. This fiber would provide for a direct, high-bandwidth link to the surface without the problems of acoustic transmission, and with reduced drag and handling problems compared to thicker ROV tethers. High-bandwidth communications from HOVs will improve their scientific productivity by involving many more researchers in the real-time experience, just as ROVs do. Similarly, AUVs will benefit from real-time human presence in the control loop. So in the new FOD HOV, the use of a micro-optical fiber similar as that used in *Nereus* is worth to be explored (Bowen et al. 2009).

The life-support subsystem includes the oxygen provision system, the carbon dioxide absorption system, the water vapor absorption system, and the odor removal. Up to now, no manned submersible has been reported to be equipped with a toilet. That is the main reason why the manned submersible could not work longer than 12 h. If this problem can be solved, people can work as long as they like in a dive. Theoretically speaking, this is not a very difficult problem nowadays.

Key Applications

Reaching the Challenger Deep

Manned and unmanned submersibles reaching the Challenger Deep are always an important event, and up to now, only two manned and four unmanned submersibles have finished that feat. On January 23, 1960, the bathyscaph *Trieste*,

piloted by Jacques Piccard and Don Walsh, made one successful dive to the depth of 10,913 m of the Challenger Deep (Piccard and Dietz 1961). In Japan, the first full ocean depth ROV “*Kaiko*” was successfully developed in 1995 (Takagawa 1995). In addition to marking the deepest point on Earth, *Kaiko* achieved more than 20 scientific dives to trenches before being tragically “lost at sea” in 2003. Since the turn of the twenty-first century, two more unmanned vehicles have been constructed: the *ABISMO* vehicle by JAMSTEC (MTS 2009) and the *Nereus* vehicle by WHOI (Bowen et al. 2009). In 2009, the hybrid AUV/ROV vehicle *Nereus* reached the Challenger Deep four times. Unfortunately, *Nereus* was lost during its 6-mile dive to

Submersible, Fig. 2 Extraordinary, unexpected life forms discovered by Alvin in the Galápagos Rift in 1977 (www.whoi.edu)

Submersible, Fig. 4 An economic setup for a research vessel. (Picture from Rainbowfish company leaflet)

the Kermadec Trench in May 9, 2014 (<http://web.who.edu/hades/a-sad-day/>). The movie director James Cameron funded a secret project to develop the full ocean depth solo manned submersible *Deepsea Challenge*. In March 26, 2012, he took his privately built one-man submersible 10,898 m down to the Challenger Deep in the Pacific Ocean's Mariana Trench (<http://www.deepseachallenge.com/>). In China, Chinese Academy of Sciences (CAS) set up a specific research project in 2013 to develop a full ocean depth ARV, and the "Hadal" ARV reached the Challenger Deep in 2016, but it was also sadly lost in 2017 which showed the great risk for unmanned submersibles.

New Scientific Discovery

Many scientific discoveries have been made by the use of various submersibles, and they are summarized in NRC (2000). For example, in 1977, scientists diving to the Galápagos Rift in *Alvin* explore seafloor vents gushing shimmering, warm, mineral-rich fluids into the cold, dark depths (www.who.edu). Amazingly, the vents are surrounded by extraordinary, unexpected life forms (Fig. 2).

Salvage of H-Bomb

In 1966, the US Navy called in *Alvin* to help find a hydrogen bomb accidentally dropped into the Mediterranean Sea. *Alvin* located the bomb, and, after the bomb skidded down a slope on the first recovery attempt, it found it again at a depth of 2,900 ft (880 m). Then, an unmanned torpedo recovery vehicle, CURV-I, became entangled in the weapon's parachute while attempting to attach a line to it. A decision was made to raise CURV and the weapon together to a depth of 100 ft (30 m), where divers attached cables to them. The bomb was brought to the surface by USS *Petrel* (Fig. 3).

Economic Setup of a Scientific Research Vessel

As is well-known, the most important cost for the use of submersibles is the cost of ship time. Therefore, a setup as shown in Fig. 4 may produce the best economic performance because researchers can carry out ocean survey with the mothership no matter day or night (Cui et al. 2014). When to a new area, the ARV will carry out a wide area

exploration first to determine the focused research area and the basic marine parameters. Then several baited landers will be deployed to shoot and catch fishes and other fauna. Finally, the manned submersible or ROV will be sent down to complete the refined operations and sampling. During the day, the landers, ARV, and HOV can work collaboratively. At night, the landers and ARV can still be used for the sea floor survey.

Subsea Connector

QingFeng Duan

Synonyms

Pipeline end termination; Underwater connector

Definition

The subsea connector is the key connection facility in subsea production system. The subsea connector, located at the pipe end of a jumper, is mainly used to interlink subsea production facilities, such as jumpers and subsea trees, jumpers and manifolds, jumpers, and PLETs (pipeline end termination).

Typical Subsea Connectors

According to the connection mechanism, the subsea connector could be classified into two main types: clamp connectors and collet connectors.

Clamp Connectors

Clamp connectors are mainly used in horizontal applications and are particularly well suited for larger bore, lower pressure connection applications. Clamp connectors are generally popular for subsea applications due to their relatively small size, small numbers of bolts to handle, and short installation time (Bai and Bai 2012). Figure 1 illustrates typical clamp connections. The clamp is the main locking device and

Subsea Connector, Fig. 1 Clamp connector. (Adapted from FMC technologies. <http://www.fmctechnologies.com/en/SubseaSystems/Technologies/SubseaProductionSystems/TieInAndFlowlines/Connectors/Clamp.aspx>. Accessed: 2018-10-14)

typically consists of two or three segments that are closed around the mating hubs by a single rotating drive screw. A metal gasket is located between the hubs that creates a seal which should be pressure tested after the connection is made, to check if the connection is tight. One of the primary advantages of clamp systems is that they are easily locked by an ROV (remotely operated vehicle) using a torque tool, eliminating the need for larger tooling.

The characteristics of clamp hubs are summarized as follows:

- The clamping device preloads two hubs as the device is tightened.
- A metal gasket is compressed between the two hubs to create a seal.
- It can be made up by divers or ROV-operated tools.
- It is faster to make up than a bolted flange because it has fewer bolts.
- Rotational alignment is not critical.

Collet Connectors

Collet connectors are the most widely used for both vertical and horizontal jumper spool connections and are available in both integral hydraulic and mechanical configurations. The connection principle is similar to that for a hub and clamp except that a series of longitudinally segmented collets replaces the clamp. The collets are activated by an annular locking cam ring. The cam ring slides axially along the collet length to either open or close the connector. The driving angle on the cam ring is typically self-locking to prevent incidental un-locking of the connector. A collet connector consists of a body and hub around in which individual “fingers” or collets are arranged in a circular pattern and attached to the body, engaging the hub to form a fully structural connection as shown in Fig. 2.

The engagement between the hub and collets is either mechanically or hydraulically actuated. Funnels or guide posts provide coarse alignment for the mating hubs. After the collet connector is landed, an ROV installs the hot stab and provides hydraulic power to the stroking cylinders, pulling the hubs together at a controlled rate. The open

Subsea Connector, Fig. 2 Collet connector. (Adapted from Cameron a Schlumberger Company. <https://www.products.slb.com/pressure-control-equipment/collet-connectors>. Accessed: 2018-10-14)

collets provide initial makeup alignment to protect the metal seal. The standard design accommodates up to $\pm 2^\circ$ angular misalignment and ± 1.5 in. axial offset. Once the hubs are mated, hydraulic collet actuating cylinders close the collet fingers to complete the connection. The collets impart a preload that gives the connection the same strength characteristics as the pipe. The seal is pressure tested after makeup via the ROV control panel.

The characteristics of collet connectors are summarized as follows:

- Collet segments are driven around a connector body and hub by an actuator ring.
- A metal gasket is compressed between the body and hub to create a seal.
- It functions by means of integral hydraulics or by an ROV-operated tool.
- It can align misaligned hubs.
- Rotational alignment is not critical.

Connector Comparison

The subsea connector choice should consider factors such as water depth, bore diameter, connection direction, installation method, environment

Subsea Connector, Table 1 Comparison between clamp and collet connectors

	Clamp connectors	Collet connectors
Structure complexity	Simpler	More complex
Duration of installation	Shorter	Longer
Connection direction	Mainly horizontal	Horizontal and vertical
Water depth	Shallower	Deeper
Environment pressure	Lower	Higher
Bore diameter	Larger	Smaller
Reliability	Lower	Higher
Cost	Lower	Higher
System integration	Nonintegral	Integral and nonintegral

pressure, reliability, cost, and so on. Table 1 shows the relative comparison between the clamp connectors and the collet connectors in applications, where the system integration is defined as:

- Integral: The hydraulic actuation system is a permanent part of the connector assembly and remains subsea.
- Nonintegral: The hydraulic actuation system is part of an installation tool. After installation, the collet connector assembly remains subsea without any hydraulic components.

Sealing Principle

The sealing principle of a subsea connector is that contact loads, derived from extrusion between hubs and gasket, cause hub surface and gasket surface deformation, which will fill the microscopic clearance between the contact surface of hubs and gasket, thereby achieving sealing performance (Zhang et al. 2017). The gasket is then the key component which affects the reliability of connectors. It plays the role of isolating fluid inside from flowing outside. It prevents the internal oil/gas to spill and seawater to enter the pipeline.

Figure 3 shows a schematic of the target subsea connector. A collet connector includes a gasket,

Subsea Connector, Fig. 3 Collet connector. (Adapted from Wang et al. 2012)

an upper hub, and a lower hub, about 12 to 24 fingers. The gasket is located in the interface between the upper and lower hubs. The lower hub is fixed to the base on the manifold, and the upper hub is connected with jumper. When the upper and lower hubs complete docking, the actuator ring is pushed down by the force from the motive source, usually several hydraulic cylinders in the installation tool. Hence, the fingers move inward. Fingers clamp the upper hub and the lower hub. The force is amplified and transmitted from hydraulic cylinders to the gasket by conic surfaces on fingers and hubs. Then, the gasket produces plastic deformation to fill the gap between two contact surfaces and it forms the initial seal. When the connector is in the operating condition, the pressure inside the pipe makes the gasket produce expansion and deformation again but still has to meet the sealing requirements. For this reason, fingers' locking force and the relative displacement between the upper hub and lower hub are both important parameters of the fingers.

Connector Assembly

The connector assembly may consist of the following components:

- Connector receiver (hub and support structure).
- Connector.
- Connector actuator.
- Connector override tool.

Figure 4 illustrates one typical collet connector assembly from OneSubsea CVC system, which includes the connector, connector receiver (hub and support structure), and connector actuator, and the connector assemblies are connected with jumper pipe and are widely used in the connection of subsea structures.

These subsea components are summarized in the following subsections.

Connector Receiver

The connector receiver is mounted on the subsea equipment (such as manifold, PLET, and tree) and includes the connector mating hub, connector alignment system, piping, and support structure. Metal-to-metal seal surfaces for each connector receiver are inlaid with a corrosion-resistant alloy.

The connector receiver should include the following components: (1) an alignment system for guiding the connector onto the mating hub (the alignment system should provide coarse alignment during the initial landing of the jumper connectors onto the connector receivers and align the connector and mating hub during final lowering within the makeup tolerances of the connector), (2) a measurement tool interface, (3) two high-quality inclinometers (90 degrees to one another) to measure the inclination of each hub directly, and (4) pad eyes for attachment of a guideline by an ROV.

The connector receiver should be designed with the following requirements in mind:

- The connector receiver should be designed to be a self-contained assembly that can be independently tested prior to integration into the subsea equipment (tree, manifold, PLET, etc.).
- The connector receiver should be field weldable to the subsea equipment (e.g., piping weld).

- The connector should be able to transfer jumper loads and connector override loads into the subsea structure (tree frame, manifold structure, PLET, etc.).
- The connector should protect critical surfaces on the mating hub during installation and retrieval.
- The connector should be designed to accept hub end caps.

Connector

The connector should be used at the end of the jumper piping to lock and seal the mating hub on the connector receiver. The connector should be equipped with the following components: (1) a mechanism (e.g., collet fingers, or dogs) designed to resist lateral and longitudinal forces that may be encountered in the process of aligning and final lowering, prior to makeup of the connection (the connector is designed to accommodate the design loads); (2) metal-to-metal seal surfaces inlaid with corrosion-resistant alloy (the seal surfaces shall be relatively insensitive to contaminants or minor surface defects and maintain seal integrity in the presence of the maximum bending moments and/or torsional moments); (3) a metal seal with an elastomeric backup capable of multiple makeups; (4) mechanical position indicators to indicate lock/unlock operations that are clearly readable by an ROV; and (5) a mechanical release override or a hydraulic secondary release system. The connector should be designed to satisfy the following requirements:

- The connector should not permanently deform the mating hub during connection.
- The connector should protect seals and seal surfaces during deployment and retrieval.
- The connector should retain the metal-to-metal seal during jumper installation and retrieval. The metal seal should be capable of being replaced by an ROV without bringing the jumper to the surface.
- The connector should be welded to the jumper pipe. The mechanical unlatch load should not exceed the allowable stresses in the connector receiver structure and piping.

Subsea Connector, Fig. 4 The OneSubsea CVC connector. (Adapted from OneSubsea a Schlumberger Company. [resources/2016/04/02/04/08/oss-cvc-connector-brochure.ashx](https://www.onesubsea.slb.com/-/media/cam/resources/2016/04/02/04/08/oss-cvc-connector-brochure.ashx). Accessed: 2018-10-14)

- The connector should provide for an external pressure test of the metal-to-metal seal after makeup using an ROV hot stab. The external pressure test is at least 1.25 times the ambient hydrostatic head. A volumetric compensator is included in the seal test circuit. This circuit is constructed with welded fittings wherever possible.

Connector Actuator

The connector actuator may be integral with the connector or independently retrievable from the connector. The connector actuator should include the following components: (1) ROV handles, which are positioned to observe critical surfaces while guiding the stabbing operation; (2) an ROV panel with pressure gauges to monitor tool functions, hot stab receptacles, etc., for operation of the soft landing system, connector makeup, and seal test (all control and seal test tubing is to be welded whenever possible; separate ROV hot stabs should be provided for each function); (3) indicators that allow the ROV to monitor tool hydraulic functions; (4) a mechanical release (override); and (5) an optional hydraulic secondary release. Note, however, that even if the hydraulic release is used, the mechanical release is still required.

The connector actuator should be designed considering the following requirements:

- The connector actuator should be designed to preclude accidental unlocking from impact loads, vibration, thermal loads, and any other loads affecting the locking mechanism. A secondary lock should be provided where self-locking mechanisms are used.
- The independently retrievable actuator should be positively locked onto the connector and protect the connector during running, retrieval, and topside handling operations.

Soft Landing System

A soft landing system for retrieval and installation should be provided to minimize the impact loads. This system is an integral part of the connector or connector actuator. It is designed to absorb impact loads while landing the jumper on the connector

receivers and to maintain the separation between the sealing surfaces when the jumper lands on the connector receiver structure. The soft landing system supports the weight of the jumper to isolate the jumper from vessel motion as the connectors are lowered onto the mating hubs. The system pulls the connector and mating hub faces together prior to locking the connector on to the hub by lowering or raising the connector from the mating hub in a controlled manner. It has mechanical position indicators to indicate a lowering operation that are clearly readable by an ROV and allows each end of the jumper to be lowered or raised independently of the other.

Definition

Subsea equipment installation technology is used to fix offshore structures in a certain position according to certain procedures and specifications and also to fix subsea equipment in a certain place according to certain methods and specifications.

Introduction

In recent years, subsea oil and gas development has become the focus of global oil and gas development, and subsea oil and gas production has increased year by year. In view of the depletion of onshore oil resources, subsea will undoubtedly be one of the priorities of the global oil strategy replacement in the future. Gulf of Mexico, West Africa, and Brazil, i.e., the “Golden Triangle,” are the three major subsea core oil and gas development areas. As indispensable equipment for subsea oil and gas development, subsea Christmas tree and subsea manifold have been paid more and more attention by the offshore oil and gas industry.

As the offshore oil industry gradually extends from shallow water to deep water, and ultra-deep water, the installation technology of subsea equipment has attracted more and more attention from China and foreign companies and researchers. Safe and efficient installation technology for

subsea oil and gas equipment is a key technical requirement that must be solved in the implementation of subsea oil and gas equipment from localization to the actual application in the South China Sea. Due to the special geographical location and topographical conditions of the South China Sea, offshore structures are vulnerable to extreme weather conditions. The impact of the marine environment is complex. When subsea oil and gas equipment passes through the splash zone, it is prone to wave breaking, large movements, and overturning. The vibration frequency of the drill pipe or wire rope could resonate with wave actions and lead to fatigue damage. Therefore installation of subsea equipment is a great challenge.

The Main Installation Methods

Subsea equipment can be installed mainly by drill pipes and wire ropes in traditional methods. The newly developed installation methods mainly include pendulous method, sheave lowering method, pencil buoy method, etc. These methods are mainly used for installation of larger subsea equipment such as subsea templates or manifolds. Mainly in Brazil, West Africa, North American Gulf of Mexico, and Norway, these new developed installation methods are relatively well developed and have been successfully used in subsea oil and gas field development projects.

Lifting Method

The lifting method is the main installation method of early subsea manifolds in deep water. There are two main forms of lifting method (Cermelli et al. 2003). One is to transport the manifold to the installation position by a supply vessel, and second is to use a wire rope to lower it to the installation location through a crane on the supply vessel or a crane barge. The other is to lower the subsea manifold to the installation location by a drill pipe. Generally speaking, the installation application depth of this lifting method is basically within 1000 m. For the installation in deeper water, the lifting method still has certain limitation due to its own load capacity and axial resonance

Subsea Equipment Installation Technology,
Fig. 1 Installation method of subsea tree using steel cable and drilling rig, respectively

problems. Figure 1 shows the installation of subsea tree using wire ropes and drilling risers.

Installation with a Drill Pipe

The installation method by means of drill pipe is a process in which the drill pipes are connected and lowered to the subsea location with the subsea equipment. This method mainly uses a supply vessel to transport subsea equipment to a movable offshore drilling device, connects the subsea equipment to the drill pipe, and then lowers it. This process also requires monitoring systems and subsea positioning systems in the installation vessels. Generally, when the water depth is less than 500 m, a guide rope is needed. The subsea equipment is lowered with the guide through four (or two diagonal) tensioned guide ropes. The end of the guide rope is connected to the subsea guide base, and the top is connected to the installation boat. But this method may be limited by the water depth and the length of the guide ropes. When the water depth is greater than 500 m, guideless installation is used. Generally, the installation of the dynamic positioning system and the cone-shaped guide funnel at the bottom of the tree are used. However, the disadvantage of this method is that it takes more time

to connect the drill pipes and has the lower efficiency in deep water.

Under this installation method, the subsea tree is firstly transported by a barge to the designated drilling platform and then uses a section of drill pipe to lower the subsea equipment to the sea floor through the moon pool. Drilling vessels capable of deepwater operations usually have a dynamic positioning function, and their main hooks can generally provide heave compensation and have a large lifting capacity, so they have the ability to install a subsea tree. However, compared with multi-purpose engineering vessels, the drilling platform or vessels have fewer resources, higher rental cost, and longer drill pipe connection time.

Installation through drill pipe is limited by the load capacity and the length of the drilling pipes, which limits the applications of this method. When the manifold/base plate is lowered, the mobile drilling device cannot perform drilling and workover operations. It leads to slower installation. Due to the high daily rent of mobile drilling units, the development cost of the entire oil field tends to be very high.

Generally, the installation process of the subsea equipment through drill pipe includes three main steps. The steps are shown in the Figs. 2, 3,

4, 5, 6, and 7. The first step is to transfer the subsea equipment from the dock to the barge and then to the installation position. In the second step, the

drill pipe is connected to the subsea equipment and lifts the equipment off the barge. The third step is to use the semisubmersible platform to locate the subsea equipment at the intended installation. Position vertically upward, and then lower the drill pipe with the subsea equipment to the sea floor.

Installation by Winch/Crane

The second traditional vertical lowering installation method is by means of a winch/crane installation. When the working water depth of the crane is satisfied, the subsea equipment can be lowered directly by a crane. When the water depth exceeds the working water depth of the crane, a winch can be used to lower the equipment to the sea floor.

The traditional vertical installation through crane/winch includes the following steps. Firstly, the subsea equipment is transported to the sea by a

tugboat or a lifting barge; secondly, connect the subsea equipment to the offshore lifting equipment, and lift it from the deck of the tugboat, and adjust it above the installation position; after completing the above connection work, the equipment is lowered, and the lowering path is monitored by a detection device. After the deployment of the subsea signal positioning system, the equipment is installed. Manifolds with a large installation weight need heavy lifting capacity and unique positioning performance, which are affected by the environment of the installation position.

The specific installation process is shown in Fig. 8.

Sheave Method

The sheave method is an effective method to solve the manifold installation problem in deep water (more than 1000 m), and it is an improvement lifting method. This method mainly uses two anchor handling and towing supply (AHTS) vessels and a semisubmersible (SS) drilling platform for the installation of subsea manifolds. The working principle is shown in Fig. 9 (Lima et al. 2008).

In practice, a pulley is installed above the subsea manifold, and two wire ropes are installed on the pulley. One of the wire ropes is connected to the SS platform and AHTS 1 through the sheave, and the other is directly connected to AHTS 2. Besides, the target manifold is connected to

Subsea Equipment Installation Technology, Fig. 7 Lowering to the bottom of the sea through the subsea equipment

Subsea Equipment Installation Technology, Fig. 8 Vertical installation of subsea equipment

the crane rope on the SS platform. After the connection is completed, the subsea manifold is lowered by the crane to a certain depth, and then detach the crane rope from the subsea manifold, so that the SS platform and AHTS 1 share the gravity of the subsea manifold by the wire rope on the sheave, and begin to lower the manifold slowly. At the same time, the AHTS 2 is used to locate the direction of the subsea manifold to avoid winding or position displacement

due to the load of wind, waves, and current when the manifold is lowered and installed. Because the SS platform has an automatic heave motion compensation function, it can reduce or even avoid the impact of wave motion on the subsea manifold sinking during the process of lowering the manifold. It has high stability and can withstand the harsh marine environment, but it requires two auxiliary vessels. Fig. 10 shows the use of this method to lower the submarine manifold. This

Subsea Equipment Installation Technology, Fig. 9 The installation method of subsea manifold by the sheave method

Subsea Equipment Installation Technology, Fig. 10 The installation of subsea manifold by the sheave method in subsea

method has been successfully used for the installation of three manifolds in the Roncador oil field in Brazil.

Pendulous Method

The pendulous method is a new installation method boldly proposed by Petrobras in 2003. It is mainly used to solve the installation of large subsea equipment in deep water and ultra-deep water, up to 3000 m water depth. In the same

year, the Brazilian Industrial Property Association granted the Brazilian petroleum company the patent right for the pendulous installation, which is one of the most advanced installation methods for large subsea equipment in ultra-deep water in the world.

The pendulous method was first applied in Brazil's Roncador oil field, and manifolds weighing 200 t and 280 t were installed at water depths of 1900 m and 1845 m, respectively.

Subsea Equipment Installation Technology,
Fig. 11 The installation principle of the pendulous method for manifold in subsea. (a) Transport vessel and submarine manifold/basket. (b) Submarine manifold/

basket is connected into the sea by the installation vessel. (c) Subsea manifold/base plate is lowered from the side of the transport vessel. (d) Manifold/base plate is lowered

Figure 11 (Machado et al. 2005; Ribeiro et al. 2006) shows the installation principle of the subsea pipe manifold pendulous method. During the installation, two work boats (the transport vessel and the installation vessel) are needed. Firstly, the subsea manifold is transported to a transport vessel equipped with a crane. The crane is used to submerge the manifold into a position, which is close to the sea surface, and then the installation cable is connected to the installation vessel (the actual installation position), as shown in Fig. 11a. At this time, the installation cable is required to be slightly shorter than the actual installation water depth, and the distance between the two vessels is about 90% of the installation cable. After the connection is completed, the carrier releases the manifold to make it slowly sag. At the same time, the installation boat controls the movement of the installation cable until it reaches the vertical

position and maintains balance, as shown in Fig. 11b. Then determine the gap with the mud line by testing the elongation of the installation cable. The subsea manifold needs to maintain a proper distance from the mud line in order to further adjust its position by installing the cable. Once the position is determined, it will be implemented.

Pencil Buoy Method

The pencil buoy method (PBM) (Risoey et al. 2007) is a subsea transportation and installation method developed by Aker. The PBM requires a lifting barge to lift the structure from a transport barge with a sufficient depth of water along the coast.

The installation process is as follows. The manifold is transported to the launching position by a barge and lifted from the barge into the seawater. The weight of the manifold is

transferred from the floating crane to the installation vessel. The rigging on the manifold is connected to the winch and pencil-shaped pontoon of the installation boat. The buoy slowly enters the water and the installation boat moves forward slowly. After towing to the installation position, the winch recovers the cables, and the weight of the manifold is transferred from the pontoon to the winch. The pontoon is recovered to the deck of the installation vessel and disconnected. The installation vessel is moved forward slowly to avoid the collision of the manifold with the installation vessel. Once stabilized, lower the manifold slowly to the ocean floor.

A pencil-shaped buoy is a steel structure with internal annular ribs. The buoy can be subdivided into many impervious tanks to meet the requirements for use under certain damage. Generally, buoys need to maintain a wet towing speed of about 3.0–3.5 knots. When the structure arrives at the installation position, the weight of the structure is retransferred from the pencil-shaped pontoon to the tug winch wire rope, and the tow cable is still connected at this stage. After the weight of the structure is completely transferred, the connection between the buoy and the structure is broken. During the load transfer process, the utility tug should move slowly forward to keep no contact between the tug stern and the pontoon. When the structure is lowered to the sea floor, the passive heave compensation system is used. In this method, the structure is transported and lowered through the splash

zone in the coastal sheltered area, not offshore. Subsea wet towing is typically not restricted by summer storms. The lowering of the structure is a standard offshore operation similar to other subsea installation methods.

Figure 12 shows the installation instructions of the pencil buoy method and the position of the pencil buoy before lowering. This installation method requires a three-purpose tugboat with standard equipment, a tailor-made pencil buoy, and a passive heave compensation system. Those are indispensable. The first generation of pencil-shaped buoys has a carrying capacity of 150 t, while the second- and recent third-generation buoys have a carrying capacity of 250 t and 350 t, respectively. Due to the action of waves and ocean currents, both the diving structure and the surface pencil-shaped pontoon suffer from complex hydrodynamic problems.

Moon Pond Wet Drag Method

Also as a method of wet towing, the moon pond wet towing method is developed by the Subsea 7 and has had several successful application examples in the North Sea, where one of the most severe sea conditions happens.

The most representative of these was the installation of a base manifold of 260 t in the Tyrihans oil field of 285 m depth in Norway in the spring of 2007 (Stock et al. 2002); see Fig. 13. Using this method, the subsea structure is firstly transported by a barge, floated and placed on the bottom of the

Subsea Equipment Installation Technology, Fig. 12 Pencil buoy method, by Aker

Subsea Equipment Installation Technology,
Fig. 13 Moon pond wet drag method

sea not far from the construction position through a multifunctional vessel, and then the subsea structure is lifted by the installation vessel the water through the moon pond, wet to the installation position, and after reaching the destination directly down to the ocean floor.

It is required that the installation of the vessel must be equipped with a winch system of considerable capacity and can provide heave compensation function. In this project example, a manifold weighs 260 t, and the winch installed with the Botnica multi-purpose vessel has only a 300 t winch system. The main reason for this efficient application to be used in this project is that this method avoids the occurrence of passing through the splash zone. The large dynamic load and the shallower water depth of the rigging itself are relatively small, so it is very suitable for the implementation of the sea area where the sea conditions are more severe. It can expand the climate windows for installation and increase operating efficiency.

Adaptability Comparison of Five Installation Methods

There are five main installation methods for subsea equipment, namely, the lifting method, the sheave method, the pendulous method, the pencil buoy method, and the moon pond wet drag method. The comparison of different installation methods is shown in Table 1. Among those methods, the lifting method has the most mature technology, and it is most widely used within a depth of 1000 m. However, due to its own load capacity, axial resonance, and high rents, there are still some limitations in the installation of subsea and ultra-deepwater manifolds. Although fiber ropes are considered instead of wire ropes, further research is needed. The sheave method can be applied to the installation of subsea manifolds with harsh sea conditions and greater than 1000 m, but it is necessary to consider the lifting capacity of vessel resources and whether related auxiliary equipment meets the conditions. The pendulous method does not require special vessels, and it can overcome the disadvantages of axial resonance and economically and efficiently install large equipment. It is the current advanced technology for ultra-deepwater and heavy equipment subsea installation, but it has higher requirements for the installation of climate windows in the sea. The pencil buoy method and the moon pond wet drag method are not applied widely in China.

Conclusions

This chapter mainly describes the installation technology and method of subsea equipment. As for the installation method of drill pipe, it has the characteristics of convenient installation, but the installation efficiency is low, and the size of the object to be installed will be limited due to the impact of the size of the moon pool. Moreover, it is not commonly used in deep water due to the limited bearing capacity of the drill string. For lifting method, the installation operation is also simple, but deep water is prone to resonance. For the pendulous method, the mass and volume of the object to be installed are not limited, and the

Subsea Equipment Installation Technology, Table 1 Performance comparison of lifting method, sheave method, pendulous method, pencil buoy method, and moon pond wet drag method

	Lifting method	Sheave method	Pendulous method	Pencil buoy method	Moon pond wet drag method
Required resources	Supply vessel or crane barge with crane or mobile drilling unit	Anchor towing vessel (2 vessels), SS drilling platform with crane	2 ordinary vessels, one of which has crane capacity	Multi-purpose boat	Multi-purpose boat
Suitable water depth (m)	Within 1000 m	More than 1000 m	Up to 1000 m	Within 1000 m	Within 1000 m
Improved capacity	Requires higher lifting capacity	Required to be medium	The lifting capacity of the installation vessel is medium	Required to be medium	Wet mop method is adopted, required to be medium
Environmental requirements	Drilling vessels are susceptible to wind and waves and have poor stability	Reduces the requirements for vessel resources and the impact of wind and waves and better requirements for installing climate windows	Low requirements for climate windows	The impact of wind and waves is small, not subject to the limitation of summer storms; suitable for sea areas with harsh sea conditions	Adopt wet towing method; the impact of wind and waves is less
Economical	Dynamically positioned drilling vessels are expensive and economically inferior	Reduced requirements for the capacity of hoisting ropes, cranes, or winches, reducing the cost of expensive vessel installation resources	Relatively scarce resources for installing vessels, PIM is more economical	Multifunctional vessel, which integrates transportation and installation, has better economy	Multifunctional vessel, which integrates transportation and installation, has better economy

requirements for working ships are also low. It is suitable for ultra-deepwater installation, but the installation is relatively complex, the carrying capacity of the wire rope is limited, and there is a risk of collision of working ships. For the sheave method, it can install equipment in deep water, with relatively loose size and weight, but there is also the risk of ship collision in operation. For pencil buoy method, it is easy to operate, and the installation equipment is not limited, and it can complete the lifting and transfer of subsea facilities in the offshore area. However, the cost of wet towing is high, and the ability of winch in deep-water installation depends on laziness and is easily affected by the environment. For the moon pond wet drag method, it requires less to install the climate window, and the smaller installation ship can install larger subsea equipment, but it

also has a high cost of wet towing, which requires very high winch capacity.

For the development of offshore oil and gas fields, it is particularly important to choose the appropriate and economical installation method when installing subsea equipment. The detailed description of installation method in this chapter is expected to provide some reference for readers.

Subsea Hazards

Hongwei An

Department of Civil Environmental and Mining,
School of Engineering, University of Western
Australia, Perth, WA, Australia

Definition

Subsea hazards are referred to natural processes that happen above seabed and have hazardous effects on structures in subsea engineering.

Subsea engineering structures are normally facing various subsea natural hazards, including subsea landslides, storms, migration of sand

waves, volcano eruptions, subsea earthquakes, etc. Within the above mentioned hazards, subsea landslide is arguably the hardest to predict and has the most catastrophic impact on subsea structures. Therefore, this entry is focused on introducing the current understanding and existing challenges about subsea landslide and its impact on subsea structures.

Formation Mechanisms of Submarine Landslide

Sediment formed on land normally is carried by river to the ocean and gets deposited on seabed due to reduced flow velocity. Continuous sediment deposition from river supply will form temporary storage on upper continental slope. However, these deposits only serve as temporary sediment storage, as instability in the slope deposits leads to periodic slope failure, landsliding, and onward downslope transport. Besides the above-mentioned slope failure, earthquake, volcanic activity, waves, tidal and gas hydrate, etc., could also trigger submarine landslide (Masson et al. 2006).

Process of Submarine Landslide

Figure 1 is a commonly accepted sketch for the processes of submarine landslide. In this diagram, large volumes of cohesive sediment fails from continental shelf break due to a triggering reason, then the sediment moves downslope and gradually breaks into smaller pieces and forms debris to avalanche in the form of falling, bouncing, and rolling; with further traveling downslope and water entrainment, the debris flow evolves into high density turbidity current. Eventually the sediment in the turbidity current resettles on seabed at locations with much deeper water depth. In the overall processes, sediment could travel hundreds kilometers distance.

There were different opinions about how far the landslide material travel before transforming into turbidity flow. Some research argued that landslide travels hundreds of kilometers without transformation into turbidity current (Bryn et al.

Subsea Hazards, Fig. 1 A sketch of subsea landslide. (The picture is from <https://theconversation.com/scars-left-by-australias-undersea-landslides-reveal-future-tsunami-potential-85982>)

2005), but some others believe this could happen near the source of the landslide (Talling et al. 2002). Through some laboratory experiments, Elverhoi et al. (2010) demonstrated that the clay-to-sand ratio is a critical parameter that governs the behavior of submarine landslide. The tests by Elverhoi et al. (2010) were conducted in a tank with 10 m in length, 3 m in depth, and 0.6 m in width and a 6° bottom slope. It was found that the slide sediment with 25% clay (by weight) tends to remain compact and attain long run-out distance and the frontal of the slide remains in laminar state and experiences hydroplaning. No obvious deposition was formed during the sliding. When the clay content is reduced to 15%, the frontal of the slide becomes turbulent and a layer of deposition is formed behind the front. When the clay content is further reduced to 5%, water intrusion happens very quickly to the front of the slide and most of the sediment settles on the seabed within a relatively short distance. Therefore the clay content is an important parameter that controls the submarine landslide process. It should be noted that all the laboratory tests were conducted with small-

scale models and there is not a clear understanding about the scaling effect yet. Therefore more research work is still need to understand the processes of submarine land slide.

Where Does Submarine Landslide Happen?

Submarine landslides are widely spread in oceans. For example, it has been identified in the region of Hawaiian Ridge (Moore et al. 1989), around Australia (Mollison et al. 2020; Hengesh et al. 2012), and in Norway Basin (Haflidason et al. 2005) and many other locations. During a landslide, significant volumes of material can be moved. Survey data shows that the moved volume can be in the scale of $10^6 \sim 10^{14} \text{ m}^3$ according to Masson et al. (2006). Some details about the Storegga Slide are given as an example. *The Storegga Slide has affected an area of approximately 95,000 km² and a sediment volume in the range of approximately 2400 ~ 3200 km³* (Haflidason et al. 2005). The slide was dated back to 8200 years ago. The Ormen

Subsea Hazards, Fig. 2 Seabed profile of Storegga slide. The dash line labels the boundary line of the slide and the Ormen Lange Gas Field is located within the slide (Masson et al. 2006)

Lange field has been identified and developed right in the scar of the Storegga slide as shown in Fig. 2 (Masson et al. 2006). The estimated recoverable gas reserve in this field is about 300 billion cubic meters and it is one of the main energy suppliers for England. The total value of the subsea structure built for the Ormen Lange gas field is about US\$12 billion. The slide risk has received particular focus for developing the field due to the historical slide (Solheim et al. 2005).

The Impact of Submarine Landslide on Subsea Pipelines

If a subsea structure, such as a pipeline is (unfortunately) located in the route of a subsea

landslide, the structure will be strongly impacted by the landslide when it passes over or around the structure. It depends on the relative location of the subsea structures to the source location of the landslide. For structures near the source location of a landslide, the sliding material is mainly in solid form. With the sliding material moving away from the source point, the sliding material will mix with water and form non-Newtonian fluid, which does not follow Newton's law about fluid viscosity. Further away from the source point, the solid material gradually settles on the seabed and only a low concentration turbidity current remains to travel further into deeper ocean. As described above, the interaction between landslide and subsea structures can be treated in three different ways: (1) structure–soil

interaction, (2) structure–Non-Newtonian fluid interaction, and (3) structure–Newtonian fluid interaction. Normally these three interactions are investigated separately using different theories.

Due to the significant volume of seabed material moved by landslide, hardly any pipelines will be able survive sliding material in solid form. However with proper research work, it is possible to design pipelines to withstand slurry flow induced by a landslide. Most of the work about pipeline–slurry interaction was carried out under the framework of fluid–structure interaction. Here it is important to introduce the concept of Newtonian fluid and non-Newtonian fluid. A Newtonian fluid is *a fluid in which the viscous stresses arising from its flow, at every point, are linearly correlated to the local strain rate—the rate of change of its deformation over time* (Panton 2006). For example, sea water and freshwater are Newtonian fluids and the viscosity are only affected by temperature. In contrast, a non-Newtonian fluid does not follow Newton’s law of viscosity. In non-Newtonian fluids, viscosity can change with stress level to be either more liquid or more solid. Landslide-induced slurry is a typical non-Newtonian fluid.

The impact force F from submarine slurry flow on pipelines are normally calculated in the form of

$$F = \frac{1}{2} \rho D U^2 C_D$$

where ρ is the density of the slurry (or turbidity current) generated from a landslide, U is the current velocity, and C_D is the drag coefficient. Slurry flow with relatively high sediment concentration is a kind of non-Newtonian fluid. C_D value under slurry flow was obtained by Zakeri (2009) and Liu et al. (2015) through numerical simulation and laboratory experiments. It was found that C_D is correlated to non-Newtonian Reynolds number ($Re_{\text{non-Newtonian}}$), which is defined as

$$Re_{\text{non-Newtonian}} = \frac{\rho U^2}{\tau}$$

where τ is the fluid shear stress and it can be calculated according to the power law model or

the Herschel-Bulkley model. Through physical model tests, Zakeri (2009) gave the normal drag coefficient (C_{D-90}) on a free-span of a subsea pipeline as below:

$$C_{D-90} = 1.4 + \frac{17.5}{Re_{\text{non-Newtonian}}^{1.25}}$$

When the pipeline is sitting on a seabed (without a gap), a reduction to drag coefficient happens as below.

$$C_{D-90} = 1.25 + \frac{11.0}{Re_{\text{non-Newtonian}}^{1.15}}$$

It should be noted that the model tests reported by Zakeri (2009) were conducted with a fixed water content (35%) and varied clay and sand contents to achieve $Re_{\text{non-Newtonian}}$ in the range of 1 to 200. With further increase of $Re_{\text{non-Newtonian}}$, C_{D-90} reaches a constant value of 1.4 asymptotically. Through numerical simulations, Zakeri (2009) also presented the drag coefficient for slurry flow in parallel to a free span in the form of

$$C_{D-0} = 0.08 + \frac{9.2}{Re_{\text{non-Newtonian}}^{1.10}}$$

The above-mentioned approach was under fluid mechanics framework. A geotechnical approach was proposed by Randolph and White (2012), in which the impact force is expressed as

$$F = \frac{1}{2} \rho D U^2 C_D + N_p s_u D$$

where $N_p s_u D$ is the bearing force term, N_p is the bearing factor, and s_u is the undrained soil strength. The prediction using this geotechnical approach was consistent with the prediction under fluid mechanics framework.

With the sediment in the slurry settling gradually, the slurry flow will experience a transition from non-Newtonian fluid to Newtonian fluid. The transition of slurry flow was investigated by Coussot (1995) using clay-water suspensions. Coussot defined two parameters, $T = \tau/\tau_c$ and $\Gamma = \mu\dot{\gamma}/\tau_c$, where τ_c is the shear strength of the

particle interaction network at rest, μ is the viscosity of the corresponding force-free particle suspension, and $\dot{\gamma}$ is the shear rate magnitude. For non-Newtonian fluid, T and Γ follow a relationship of $T = 1 + K\Gamma^n$, where K and n are material parameters (see details in Coussot 1995). For Newtonian fluid, T and Γ are equal to each other. Coussot (1995) found that clay slurry with $\Gamma > 50$ is in the Newtonian fluid regime and slurry with $\Gamma < 0.3$ is in the non-Newtonian fluid regime. In the range of $0.3 < \Gamma < 50$, a gradual transition from non-Newtonian to Newtonian flow happens. Therefore, for slurry flow with $\Gamma > 50$, the drag coefficient measured in Newtonian fluid should be used. A comprehensive summary about the C_D on a pipeline in Newtonian fluid flow has been given by Sumer and Fredsøe (2006). It was found that the Reynolds number based on pipe diameter ($Re_D = UD/\nu$) has a strong effect on the value of $C_D - 90$ in Newtonian fluid due to the boundary layer on the pipe surface transition from laminar to turbulent state. However, limited work has been done for this effect under non-Newtonian fluid condition.

Remaining Challenges

Although a significant amount of work has been carried out in the past few decades on submarine landslides and its impact on subsea engineering, it still remains a great challenge in many aspects. The challenges related to offshore engineering are summarized as follows.

1. A good understanding about the whole landslide process is still to be developed. This understanding is extremely important for design of subsea structures with impact from subsea landslide. It will also help to predict landslides.
2. The interaction between submarine landslide and pipelines has been studied reasonably well, but its impact to other subsea structures (such as piles, foundations, subsea well, etc.) is still to be examined.
3. The fundamental understanding about the interaction between non-Newtonian slurry

flow and structures is still to be explored. Rich fluid dynamic phenomena have been identified for Newtonian fluid flow around subsea pipelines, such as flow separation, vortex shedding, drag crisis, etc. It is expected that the non-Newtonian flow could have some fundamentally different flow behavior to be investigated.

Subsea system; Underwater production system

Definition

The industries of oil and gas areas are facing growing competition, and the onshore resources in some areas almost reached an exhausted state. With the increasing energy demands around the globe, the oil and gas development activities in deep water become more and more urgent. As the operation environment of this equipment corresponds to the deep sea or ultrahigh deep sea, traditional equipment that has been previously used in offshore and onshore environments is not appropriate for this field development. Therefore, to collect oil and gas in the deep sea, equipment that is specialized for the deep sea needs to be developed. As an important support of floating production facilities (e.g., tension leg platform (TLP), semisubmersible platform, spar platform,

floating production storage and offloading (FPSO)), the subsea production system plays a dominated role in the exploration of deepwater oil and gas fields.

As the oil and gas fields move further offshore into deeper water and deeper geological formations in the quest for reserves, the technology of drilling and production has advanced dramatically. The latest subsea technologies have been proven and formed into an engineering system, namely, the subsea production system, which is associated with the overall process and all the equipment involved in drilling, field development, and field operation. The subsea production system consists of the following components (Fig. 1):

- Christmas trees
- Processing systems
- Tie-in and pipeline systems
- Umbilical and riser systems
- Power and control systems
- Subsea structures and manifold system

The most advantages of the SPS implement are economic superiority and time efficiency. Additionally, it is insensitive to water depth and is not easily affected by the environments of wind and waves in the sea surface. These merits make the SPS a system with good safety and high reliability, as well as wide application range.

Christmas Trees

Christmas trees are used on both surface and subsea wells. It is common to identify the type of tree as either “subsea tree” or “surface tree.” Each of these classifications has a number of variations. Examples of subsea include conventional, dual bore, mono bore, TFL (through flowline), horizontal, mudline, mudline horizontal, side valve, and TBT (through-bore tree) trees. The deepest installed subsea tree is in the Gulf of Mexico at approximately 9000 ft (2700 m). (Current technical limits are up to around 3000 m and working temperatures of –50 °F to 350 °F with a pressure of up to 15,000 psi.)

Subsea Production System, Fig. 1 Composition of subsea production system (Bai and Bai 2019)

The primary function of a tree is to control the flow, usually oil or gas, out of the well. (A tree may also be used to control the injection of gas or water into a nonproducing well in order to enhance production rates of oil from other wells.) When the well and facilities are ready to produce and receive oil or gas, tree valves are opened, and the formation fluids are allowed to go through a flowline. This leads to a processing facility, storage depot, and/or other pipeline eventually leading to a refinery or distribution center (for gas). Flowlines on subsea wells usually lead to a fixed or floating production platform or to a storage ship or barge, known as a floating storage offloading (FSO) vessel, or floating processing unit (FPU), or floating production storage and offloading (FPSO) vessel.

A tree often provides numerous additional functions including chemical injection points, well intervention means, pressure relief means, monitoring points (such as pressure, temperature, corrosion, erosion, sand detection, flow rate, flow composition, valve and choke position

feedback), and connection points for devices such as downhole pressure and temperature transducers (DHPT). On producing wells, chemicals or alcohols or oil distillates may be injected to preclude production problems (such as blockages).

Functionality may be extended further by using the control system on a subsea tree to monitor, measure, and react to sensor outputs on the tree or even down the well bore. The control system attached to the tree controls the downhole safety valve (SCSSV, DHSV, SSSV) while the tree acts as an attachment and conduit means of the control system to the downhole safety valve. Tree complexity has increased over the last few decades. They are frequently manufactured from blocks of steel containing multiple valves rather than being assembled from individual flanged components. This is especially true in subsea applications where the resemblance to Christmas trees no longer exists given the frame and support systems into which the main valve block is integrated.

Note that a tree and wellhead are separate pieces of equipment not to be mistaken as the same piece. The Christmas tree is installed on top of the wellhead. A wellhead is used without a Christmas tree during drilling operations, and also for riser tieback situations that later would have a tree installed at riser top. Wells being produced with rod pumps (pump jacks, nodding donkeys, grasshopper pumps, and so on) frequently do not utilize any tree owing the absence of a pressure-containment requirement.

Processing Systems

Subsea processing is used to increase the hydrocarbon production in a cost-optimized way for new field developments, tiebacks, and existing facilities. It can also enable production in marginal fields. The main types of subsea processing include combinations of oil-water separation, gas/liquid separation, gas-liquid-multiphase boosting, and water injection in the oil or gas field's wellstream on the seafloor. The systems can:

- Increase hydrocarbon recovery
- Optimize field development solutions
- Debottleneck existing production facilities (risers, topside process capacity)
- Allow subsea produced water separation and reinjection
- Allow subsea gas/liquid separation and boosting
- Enable long-distance subsea tiebacks
- Allow production in harsh environments and remote locations
- Allow seawater treatment for injection

While subsea developments have been made possible by technologies such as subsea trees, risers, and umbilicals, subsea processing has been an elusive solution for many years. Whether describing subsea separation, reinjection, or boosting, subsea processing has helped to revolutionize offshore developments worldwide.

With production equipment located on the seafloor rather than on a fixed or floating platform,

subsea processing provides a less expensive solution for myriad offshore environments. Originally conceived as a way to overcome the challenges of extremely deepwater situations, subsea processing has become a viable solution for fields located in harsh conditions where processing equipment on the water's surface might be at risk. Additionally, subsea processing is an emergent application to increase production from mature or marginal fields.

Subsea processing can encompass a number of different processes to help reduce the cost and complexity of developing an offshore field. The main types of subsea processing include subsea water removal and reinjection or disposal, single-phase and multiphase boosting of well fluids, sand and solid separation, gas/liquid separation and boosting, and gas treatment and compression.

Tie-In and Pipeline Systems

Subsea flowlines are used for the transportation of crude oil and gas from subsea wells, manifolds, offshore process facilities, loading buoys, S2B (subsea to beach), as well as reinjection of water and gas into the reservoir. Achieving successful tie-in and connection of subsea flowlines is a vital part of a subsea field development.

Vertical Tie-In Systems

Vertical connections are installed directly onto the receiving hub in one operation during tie-in. Since the Vertical Connection System does not require a pull-in capability, it simplifies the tool functions, provides a time-efficient tie-in operation, and reduces the length of rigid spools.

Horizontal Tie-In Systems

Horizontal tie-in may be used for both first-end and second-end tie-in of both flowlines, umbilicals and jumper spools. The termination head is hauled in to the tie-in point by use of a subsea winch. Horizontal tie-in may be made up by clamp connectors operated from a tie-in tool, by integrated hydraulic connectors operated through the ROV, or by non-hydraulic collet connectors

with assistance from a connector actuation tool (CAT) and ROV. Horizontal connections leave the flowline/umbilical in a straight line, and it is easy to protect if over trawling from fishermen should occur.

Pipeline Systems

Subsea flowlines are the subsea pipelines used to connect a subsea wellhead with a manifold or the surface facility. The flowlines may be made of flexible pipe or rigid pipe, and they may transport petrochemicals, lift gas, injection water, and chemicals. For situations where pigging is required, flowlines are connected by crossover spools and valves configured to allow pigs to be circulated. Flowlines may be single pipe, or multiple lines bundled inside a carrier pipe. Both single and bundled lines may need to be insulated to avoid problems associated with the cooling of the produced fluid as it travels along the seabed. Subsea flowlines are increasingly being required to operate at high pressures and temperatures. The higher pressure condition results in the technical challenge of providing a higher material grade of pipe for high-pressure, high-temperature (HP/HT) flowline projects, which will cause sour service if the product includes H₂S and saltwater. In addition, the higher-temperature operating condition will cause the challenges of corrosion, down-rated yield strength, and insulation coating. Flowlines subjected to HP/HT will create a high effective axial compressive force due to the high fluid temperature and internal pressure that rises when the flowline is restrained (Davalath et al. 2002).

Umbilical and Riser Systems

Umbilical Systems

Subsea umbilicals are deployed on the seabed (ocean floor) to supply necessary control, energy (electric, hydraulic), and chemicals to subsea oil and gas wells, subsea manifolds, and any subsea system requiring remote control, such as a remotely operated vehicle. Subsea intervention umbilicals are also used for offshore drilling or workover activities.

Riser Systems

The production riser is the portion of the flowline that resides between the host facility and the seabed adjacent to a host facility. Riser dimensions range from 3 to 24 (76.2–609.6 mm) in diameter. Riser length is defined by the water depth and riser configuration, which can be vertical or a variety of waveforms. Risers can be flexible or rigid. They can be contained within the area of a fixed platform or floating facility, run in the water column.

Subsea Control Module (SCM)

The SCM is an independently retrievable unit. SCMs are commonly used to provide well control functions during the production phase of subsea oil and gas production. Typical well control functions and monitoring provided by the SCM are as follows:

- Actuation of fail-safe return production tree actuators and downhole safety valves
- Actuation of flow control choke valves, shutoff valves, etc.
- Actuation of manifold diverter valves, shutoff valves, etc.
- Actuation of chemical injection valves
- Actuation and monitoring of surface-controlled reservoir analysis and monitoring systems, sliding sleeve, choke valves
- Monitoring of downhole pressure, temperature, and flow rates
- Monitoring of sand probes and production tree and manifold pressures, temperatures, and choke positions

SCM Components

The typical SCM receives electrical power, communication signals, and hydraulic power supplies from surface control equipment. The subsea control module and production tree are generally located in a remote location relative to the surface control equipment. Redundant supplies of communication signals and electrical and hydraulic power are transmitted through umbilical hoses and cables ranging from 1000 ft to several miles in length, linking surface equipment to subsea

equipment. Electronics equipment located inside the SCM conditions the electrical power, processes communication signals, transmits status, and distributes power to solenoid piloting valves, pressure transducers, and temperature transducers.

The subsea electrical module (SEM) is fed with AC power directly from the EPU. It normally incorporates two AC-DC converters and output to DC bus bars (typically 24 and 5 V). Actuation of the electrohydraulic valves is tapped into a 24-bus bar, while the sensors are tapped into a 5-V bus bar.

Low-flow-rate solenoid piloting valves are typically used to pilot high-flow-rate control valves. These control valves transmit hydraulic power to end devices such as subsea production tree valve actuators, choke valves, and downhole safety valves. The status condition of control valves and their end devices is read by pressure transducers located on the output circuit of the control valves.

Auxiliary equipment inside the typical SCM consists of hydraulic accumulators for hydraulic power storage, hydraulic filters for the reduction of fluid particulates, electronics vessels, and a pressure/temperature compensation system. Previous devices have used an oil-filled chamber to compensate for hydrostatic pressure increases outside of the device during use to keep seawater away from cable assemblies.

The SCM is typically provided with a latching mechanism that extends through the body of the SCM and that has retractable and extendable dogs or cams thereon to engage a mating receptacle in a baseplate.

SCM Control Mode Description

The SCM utilizes single LP and HP hydraulics, supplied from the umbilical system. Each supply has a “last chance” filter before supply is manifolded to the main supply and pilot supply ports of the solenoid-operated pilot valves.

The LP supply has an accumulator that is mounted internally to the SCM. The HP supply may also have an accumulator. A pressure transducer measures the HP and LP supply pressures for display at the MCS. There are four pilot valves: three on the LP for tree valves and choke

and one on the HP for the downhole safety valve (DHSV), usually referred to the surface-controlled subsurface safety valve (SCSSV). The hydraulic return line has a nonreturn valve to vent used fluid to the sea and prevent seawater ingress.

Valve Actuation

Most of the pilot valves have two solenoids to operate them, one to open and one to close. The solenoids are driven by the solenoid drivers in the SEM.

To open a tree valve, the appropriate solenoid is commanded from the MCS, and the microprocessor in the SEM activates the solenoid driver, which energizes the open solenoid for 2 s. (typically; this may be adjusted at the MCS). This allows hydraulic fluid to flow into the function line to the tree valve actuator. The pressure in this line will rise very quickly to a value that allows the valve to latch open hydraulically. Thereafter, the valve will remain open as long as the hydraulic supply pressure remains above about 70 bar.

To close a tree valve, the close solenoid is energized in a similar manner to the open solenoid. This causes the spool in the pilot valve to move, venting the hydraulic fluid from the tree valve actuator. The used fluid is vented to sea via a nonreturn valve.

Choke Operation

The choke has two hydraulic actuators, one to open and one to close, that move the choke via a pawl and ratchet mechanism.

The choke is moved by applying a series of hydraulic pressure pulses to the appropriate actuator. On each pressurize/vent cycle, the choke will move by one step. To provide these pressure pulses, the SCM has two pilot valves, one for opening the choke and one for closing the choke. These valves are not hydraulically latched and will only pass hydraulic fluid when the solenoid is energized.

To operate the choke, the MCS sends a series of commands to the SCM. For example, if the operator wishes to move the choke by 20 steps, the MCS will send 20 appropriately timed valve commands to the SCM to energize the appropriate solenoid.

Subsea Structures and Manifold System

Subsea manifold is a flow-routing subsea hardware (subsea flow router) that connects between subsea trees and flowlines. It is used to optimize the subsea layout arrangement and reduce the quantity of risers connected to the platform. If connected to dual flowlines, the manifold can typically accommodate pigging and have the capability of routing production from a particular tree to a particular flowline (Laurent et al. 2006).

Subsea Manifold Types

There are several manifold types and it is the field layout that determines the type of manifold required.

- Template manifold

Template manifold is a drill-through structure designed to house multiple subsea Christmas trees on top of it and gather/route flow at the same time. It is required when subsea Christmas trees are grouped side by side. Trees are connected directly into the manifold via mandrels when installed.

Template manifold must be fabricated and installed before the start of drilling, which gives less schedule flexibility. It does not allow the reuse of exploration wells because they are typically not grouped together. Statoil's Norne in North Sea has template manifold.

- Cluster manifold

Cluster manifold is a stand-alone structure designed to direct fluids for multiple subsea Christmas trees placed around it. It typically can accommodate 4–8 wells per manifold. Both the TOTAL and Shell's manifolds shown in the picture are cluster manifolds. When subsea Christmas trees are grouped closely in a central location (but not side by side), either a cluster manifold or a PLEM is required depending on the number of trees anticipated. A Daisy Chain field layout has the same manifold requirements.

- Pipeline end manifold (PLEM)

For large-diameter trunk lines, PLEMs may be necessary to support the tie-in spool connection

systems/SSIV and hence aren't always associated with wellheads. For example, some of the large LNG projects use a PLEM to host multiple flexible gas risers and the diverless pig launching facilities which then connect to the gas export pipeline via a PLET and diverless-installed spool. A PLEM generally connects directly to a subsea flowline without the use of a pipeline end termination (PLET).

Manifold Components

A manifold is typically composed of the following major components:

- Pipework and valves – contain and control the production and injection fluids.
- Structure framework – protects and supports the pipework and valves.
- Subsea connection equipment – allows subsea tie-in of multiple pieces of equipment. Types include vertical, horizontal, and stab-and-hinge-over connections.
- Foundation – interface between the manifold structure and seabed.
- Controls equipment – allows the remote control of any hydraulically actuated subsea manifold valves and the monitoring of production and injection fluids. Control pods may be either internal or external to the manifold.

Framework Structure

The framework is a welded structure to provide support for the pipework and valves and contain the foundation interface structure. The pipework is allowed to float inside the framework within limits and it is not rigidly attached to the frame. The frame can also be used for lifting and landing of the jumper tie-in tools. In addition, a major function of the framework structure is often to provide mechanical protection to the internal pipework and equipment from third-party interactions, as well as often aiming to facilitate over-trawling by fishing gear.

Definition

In general, a typical suction pile structure is a closed-top, open-bottom steel structure or a steel-concrete composite structure with a closed drain/air outlet at one end and a pump-connected suction outlet (Figs. 1 and 2). The suction pile is similar to the buckled bucket, so it is also called bucket foundation. It has many advantages such as (a) precise positioning in deep water, (b) ease of removal and relocation, (c) less dependency on heavy installation equipment, and (d) large diameter that can develop considerable resistance against significant loads generated by top structures, so it is widely used in the foundation structure of subsea production system (SPS), which is suitable for deep and ultra-deep subsea environment.

When suction pile works, it sinks to a certain depth under the action of dead weight firstly. With the help of pump system, it sucks out the water inside the pile barrel to form negative pressure in the closed barrel body, thus generating downward

Suction Piles, Fig. 1 Suction pile. (<http://www.cranemaster.com/wp-content/uploads/2016/11/References-offshore-installation-suction-pile-bourbon-passive-heave-compensation-02.jpg>)

Suction Piles, Fig. 2 Suction pile structural representation

thrust and pressing the pile into the predetermined depth in the soil.

When the suction pile is recovered, the pump system works in reverse and pours water into the pile barrel to make the internal pressure greater than the external pressure. The positive pressure difference between inside and outside is used to push the pile out of the mud surface.

The design of suction pile should consider the following key factors: design of overall lifting facilities for suction pile jacket; the maximum yaw angle of jacket transport vehicle, vessel, and transport process; college core for suction pile lifting; suction pile jacket installation; and anti-erosion measures for suction pile foundation.

Scientific Fundamentals

History of Suction Pile

The innovative idea of using negative pressure sinking was firstly introduced by Statoil in the Gullfaks field in the North Sea in 1985 (Tjelta et al. 1986). It conducted a large-scale offshore penetration test so as to gained valuable experience in the use of skirt foundations on

gravity-based platforms using negative pressure. To further understand the performance of such foundations, a series of model tests combining static and cyclic loads to simulate the loading of subsea platforms are carried out. In 1990, Norwegian Aker Engineering Company proposed the use of under pressure caisson piles instead of the traditional pile foundation, and the entire design was completed in 1994 after a series of on-site insertion tests were carried out on the actual seabed to increase the understanding of the structural form. The successful installation of the Europipe 16/11E jacket in the North Sea in July 1994 marked the entry of this technology into the practical phase of industrialization (Bye et al. 1995), and the first suction pile moorings for permanent use were installed 1995 in 100–200 m water depth and for catenary anchor lines (Sparrevik 1996), and the first step into deep water using suction piles moorings was taken in Brazil in 1997 for Petro-bras P-19 and P-26 floaters at the Marlin field (Mello et al. 1998). Today, the suction pile is one of the most common foundation forms of SPS, and there are hundreds of suction piles operative in permanent mooring systems around the world.

Working Principle of Suction Pile

Suction pile is installed with the aid of suction (under pressure) created within the cylinder. The creation of the suction can be with the aid of a suction source, such as a pump, that is mounted on, close to, or at a distance from the suction pile. The applied level of the suction can be substantially constant, smoothly increase or decrease, or comprise a number of pulses. After use, the suction pile can be removed by creating an overpressure within the cylinder by pumping in water.

Suction pile is somewhat misleading since it is also used for short piles with large diameter. The aspect ratio L/D (length over diameter) for some suction piles is close to 1 and is clearly not a pile in a classical sense. Suction pile has a number of advantages over conventional offshore foundations, mainly being quicker to install than pile and being easier to remove during decommissioning. This methodology is now used extensively worldwide for anchoring large offshore installations to the seafloor at great depths,

or where the seabed is soft clays or low strength sediments.

Installation of Suction Pile

Flow chart of suction pile installation process (Fig. 3):

The installation of suction pile usually has three steps as shown in Fig. 4: deployment, self-penetration, and embedment.

In the first deployment step, the suction pile was handled, transported, and installed by an off-shore construction vessel, with or without an A-frame. Since gravity is required to insert into the seabed at the initial stage of installation, a thick steel plate or concrete layer is usually used as the counterweight at the closed end. The side wall of the barrel is rolled with steel plate. In order to prevent buckling of the barrel wall, it is usually necessary to weld various kinds of strong ribs in the barrel body. The installation vessel first approached the suction pile, lifted it up, moved it out to the open water, and then lowered the suction pile from the water surface to the water bottom, removably securing the pumping unit to the top of suction pile either before or after the lowering of the pile. Loads are resisted through the structure with mooring padeyes or pile top footings to the soil via direct bearing and skin friction.

Next step is self-penetration; the suction pile is placed on the bottom of the sea, and the pile's lower edge is embedded in the soil by the weight of the pile. When the suction pile was correctly positioned and oriented, the crane further lowered the pile slowly until the pile penetration into the seafloor soil stopped due to its own weight. The suction pile can penetrate up to 60% of its length under its own weight, depending on soil conditions and the pile properties.

Finally is the embedment step, the pump is pumped outward with the help of the submersible pump installed on the pile cap and a remote-operated vehicle (ROV). At the same time, the amount of water pumped out exceeds the amount of water infiltrated from the bottom, resulting in the reduction of the internal pressure of the pile tube. When the vertical downward pressure caused by the pressure difference between the inside and outside of the pile cylinder exceeds the resistance of the soil to the pile cylinder, the pile cylinder can be continuously pressed into the soil until the top surface of the pile cylinder contacts with the seabed, and the pile sinking stops. At this point, the submersible pump can be removed, and the pressure difference between the inside and outside of the pile cylinder gradually disappears. The pressure in the cylinder reverts to the same pressure as the environment.

Suction Piles, Fig. 4 Suction pile installation

Key Technology

Calculation Methods for Bearing Capacity

The axial and lateral bearing capacities of suction piles need to be evaluated in the design process, and there are three methods which normally used in the evaluation: limit equilibrium method, semi-empirical beam column analysis method, and finite element method (Wang and Pan 2011).

Limit equilibrium method: The determination of reasonable failure mode of suction pile is mainly based on the combination of experimental observation, numerical analysis, and engineering experience. The disadvantage of this method is that the assumption is introduced and the analysis is approximate. The theoretical solution has some limitations. However, this method is the theoretical basis for the calculation of the bearing capacity of suction pile. The sliding surface is assumed first, and the ultimate bearing capacity is calculated according to static equilibrium and failure criteria.

Semiempirical beam column analysis method: It is called semiempirical method because the beam column method relies on a series of

empirical rules to express the soil resistance without defining the failure mechanism. Instead, the soil resistance is expressed by a series of uncoupled, nonlinear soil springs (P-y curves) along the pile length. Beam column method is based on the integration of experimental and analytical results, and it is difficult to obtain general results.

Finite element method: The finite element method program can automatically find the critical failure mechanism with high calculation accuracy and can consider nonlinear factors, which can be used to simulate complex soil properties. Of course, there are also corresponding requirements, for example, advanced numerical analysis requires specific knowledge, and the establishment of appropriate models takes a long time.

Large Deformation Analysis (LDA) of Penetration Process

The penetration process of suction pile installation has one of the most challenging topics in computational geomechanics which is LDA, particularly in problems involving complicated structure-soil interaction. The total Lagrangian and the update

Lagrangian finite element approaches cannot solve this problem due to the mesh being seriously distorted. To capture large deformation phenomena that occur frequently in suction pile penetration process, the traditional numerical approaches established within Lagrangian framework are replaced by, for example, those based on the framework of arbitrary Lagrangian-Eulerian (ALE).

Among a variety of ALE approaches, three FE methods are widely used in research and industry for analysis of geotechnical engineering problems: the remeshing and interpolation technique by small strain (RITSS), an efficient ALE (EALE) approach, and the coupled Eulerian-Lagrangian (CEL) approach (Wang et al. 2015).

The RITSS approach was originally presented by Hu and Randolph (1998), in which the deformed soil is remeshed periodically and Lagrangian calculation is implemented through an implicit time integration scheme. The advantage of RITSS is that the remeshing and interpolation strategy can be coupled with any standard FE program, through user-written interface codes.

The EALE approach is based on the operator split technique proposed by Benson (1989). This method is a well-known variant of r-adaptive FE methods, which have been designed to eliminate possible mesh distortion by changing and optimizing the location of nodal points without modifying the topology of the mesh.

In the CEL method, the element nodes move temporarily with the material during a Lagrangian calculation phase, which is followed by mapping to a spatially “fixed” Eulerian mesh. The calculation in the Lagrangian phase is conducted with an explicit integration scheme. In contrast to RITSS and EALE, an element in CEL may be occupied by multiple materials fully or partially, with the material interface and boundaries approximated by volume fractions of each material in the element. The comparatively rigid structural part is usually modeled as a Lagrangian body and the soils as Eulerian materials. A “general contact” algorithm by means of an enhanced immersed boundary method describes frictional contact between Lagrangian and Eulerian materials.

Typical Application

Dalia SPS

The SPS of Dalia (Lafitte et al. 2007) was the largest subsea order in offshore history at that time in 2002, with 71 wells, 71 drill through horizontal trees, 9 6-slot production manifolds, 2 work-over systems, and a complex control and chemical injection system. Deepwater environment with an external pressure of up to 145 bars with soft soil conditions requires installation of subsea equipment using suction piles. Each manifold assembly consists of a foundation bottom structure and manifold. The foundation bottom structure comprises a suction pile and a manifold support structure, which is adjustable in level to ± 5 degrees. The size of its suction pile is diameter $6.2 \text{ m} \times 11.8 \text{ m}$ and 31 tonnes (Fig. 5).

BP King Subsea Pump

BP King is an oil field located in the Gulf of Mexico. It consists of three wells, and the wells are located in water depths ranging from 1520 to

Suction Piles, Fig. 5 SPS manifold module with suction pile

1655 m. At the time of 2005, the deepest installed subsea multiphase pump was situated in 900 m of water, and the longest step-out was 9 km. The pump equipment suitable for a depth of approximately 1700 m and a step-out of 27 km were required in the King pump project. In November 2007, the BP King subsea pumps (Davis et al. 2009) were commissioned in record-breaking water depth of 1700 m offshore Louisiana. Two twin-screw multiphase pumps were installed with a 27 km tieback to the Marlin Tension Leg Platform. The King pump systems comprise of a pump manifold and a separately retrievable multiphase pump module; they were installed as fully assembled units onto the suction pile foundations.

Perdido Development

The Perdido (Denney 2010) development includes the Great White, Silvertip, and Tobago fields and is in the Perdido basin and fold belt in the Alaminos Canyon protraction area. This area is 200 miles south of Freeport, Texas, USA, and 8 miles north of the Mexico maritime border. All three fields are developed with subsea wells tied back to a spar with full offshore processing capabilities and pipelines for export. For the Perdido development, two production manifolds were

located under the host spar structure. Each manifold has two main headers, and each header is connected to one of the five artificial lift subsea boosting systems. In addition, 22 wells were batch set before the manifolds, so suction piles were used to provide the foundation support, instead of the traditional mudmat in order to minimize the need of an extensive flat level area with minimum elevation tolerance.

Cascade and Chinook Subsea Development

Cascade and Chinook (Masson et al. 2011) are two separate fields which located in the Walker Ridge Outer Continental Shelf leasing area of the central Gulf of Mexico. The Cascade and Chinook Subsea Development risers are the deepest production risers in the world by 2011(2500 m depth,). And each field is independently developed but shared a FPSO (floating production, storage, and offloading) unit, which located between the two fields, and export infrastructure including two shuttle tankers and a gas export pipeline. The suction piles which diameters of 5.49 m (Fig. 6) were installed by Technip's Deep Blue pipe laying ship in August 2009. The riser suction piles are horizontally offset 371.86 m from the center of the FPSO turret buoy. Similarly,

Suction Piles, Fig. 6 The riser suction pile on supply boat

Suction Piles, Fig. 7 The hoisting of YC 13-4 gas field PLEM with three suction piles

the manifold and the pump basement in the Cascade and Chinook used the same suctions as the lower riser components, which was also performed with the Deep Blue and managed by the same project.

YC 13-4 Gas Field

YC 13-4 gas field (Huang et al. 2014) is located in the South China Sea and belongs to the marginal oil and gas field at the water depth about 89 m. According to the requirement of YC 13-4 gas field development, a new type underwater manifold which has the suction pile foundation was designed. The soil of seabed in YC 13-4 gas field is relatively soft, and the traditional method of plate-pile fixed is not reliable. Therefore, both PLET and PLEM have three suction piles. The whole structure is connected by three independent suction piles through the frame. The advantages of suction pile fixation are fully verified in the installation process. A guide column and a lock pin structure are arranged on the suction pile for fixing the connection with the upper pipe manifold, which can realize leveling well and prevent the fishing net from towing. It can be well adjusted to the level and prevent from the fishing nets dragging (Fig. 7).

SMB: Surface Marker Buoy

Definition

A surface buoy is a device floating on the water surface and can have many purposes. It can be anchored (stationary) or allowed to drift with ocean currents. There are many types of buoys for different purposes.

Scientific Fundamentals

To keep the surface buoy floating on the water surface, there must be some forces acting on it, among which the most important force is buoyancy.

Archimedes' Principle

Archimedes' principle is named after Archimedes of Syracuse, who first discovered this law in 212 B.C (Acott 1999). For objects, floating and sunken, and in gases as well as liquids (i.e., a fluid), Archimedes' principle may be stated thus in terms of forces: Any object, wholly or partially immersed in a fluid, is buoyed up by a force equal to the weight of the fluid displaced by the object with the clarifications that for a sunken object the volume of displaced fluid is the volume of the object, and for a floating object on a liquid, the weight of the displaced liquid is the weight of the object.

More tersely : Buoyancy = weight of displaced fluid.

Archimedes' principle does not consider the surface tension (capillarity) acting on the body (Floater clustering 2005), but this additional force modifies only the amount of fluid displaced and the spatial distribution of the displacement, so the principle that Buoyancy = weight of displaced fluid remains valid.

The weight of the displaced fluid is directly proportional to the volume of the displaced fluid (if the surrounding fluid is of uniform density). In simple terms, the principle states that the buoyancy force on an object is equal to the weight of the fluid displaced by the object, or the density of the fluid multiplied by the submerged volume times the gravitational acceleration, g . Thus, among completely submerged objects with equal masses, objects with greater volume have greater buoyancy. This is also known as upthrust.

Assuming Archimedes' principle to be reformulated as follows,

$$\begin{aligned} & \text{apparent immersed weight} \\ &= \text{weight of object} \\ & \quad - \text{weight of displaced fluid} \end{aligned} \quad (1)$$

then inserted into the quotient of weights, which has been expanded by the mutual volume

$$\frac{\text{density of object}}{\text{density of fluid}} = \frac{\text{weight}}{\text{weight of displaced fluid}} \quad (2)$$

yields the formula below. The density of the immersed object relative to the density of the fluid can easily be calculated without measuring any volumes:

$$\frac{\text{density of object}}{\text{density of fluid}} = \frac{\text{weight}}{\text{weight} - \text{apparent immersed weight}} \quad (3)$$

(This formula is used for example in describing the measuring principle of a dasymeter and of hydrostatic weighing.)

Forces and Equilibrium

The equation to calculate the pressure inside a fluid in equilibrium is:

$$f + \text{div } \sigma = 0 \quad (4)$$

where f is the force density exerted by some outer field on the fluid and σ is the Cauchy stress tensor. In this case the stress tensor is proportional to the identity tensor:

$$\sigma_{ij} = -p\delta_{ij} \quad (5)$$

Here δ_{ij} is the Kronecker delta. Using this the above equation becomes:

$$f = \nabla p \quad (6)$$

Assuming the outer force field is conservative, that is it can be written as the negative gradient of some scalar valued function:

$$f = -\nabla\Phi \quad (7)$$

Then:

$$\nabla(p + \Phi) = 0 \Rightarrow p + \Phi = \text{const} \quad (8)$$

Therefore, the shape of the open surface of a fluid equals the equipotential plane of the applied outer conservative force field. Let the z -axis point downward. In this case the field is gravity, so $\Phi = -\rho_f g z$ where g is the gravitational acceleration, ρ_f is the mass density of the fluid. Taking the pressure as zero at the surface, where z is zero, the constant will be zero, so the pressure inside the fluid, when it is subject to gravity, is

$$p = \rho_f g z \quad (9)$$

So pressure increases with depth below the surface of a liquid, as z denotes the distance from the surface of the liquid into it. Any object with a nonzero vertical depth will have different pressures on its top and bottom, with the pressure on the bottom being greater. This difference in pressure causes the upward buoyancy force.

The buoyancy force exerted on a body can now be calculated easily, since the internal pressure of the fluid is known. The force exerted on the body can be calculated by integrating the stress tensor over the surface of the body which is in contact with the fluid:

$$\mathbf{B} = \oint \sigma d\mathbf{A} \quad (10)$$

The surface integral can be transformed into a volume integral with the help of the Gauss theorem:

$$\begin{aligned} \mathbf{B} &= \oint \text{div } dV = - \int \mathbf{f} dV = -\rho_f \mathbf{g} \int dV \\ &= -\rho_f \mathbf{g} V \end{aligned} \quad (11)$$

where V is the measure of the volume in contact with the fluid, that is the volume of the submerged part of the body, since the fluid does not exert force on the part of the body which is outside of it.

The magnitude of buoyancy force may be appreciated a bit more from the following argument. Consider any object of arbitrary shape and volume V surrounded by a liquid. The force the liquid exerts on an object within the liquid is equal

to the weight of the liquid with a volume equal to that of the object. This force is applied in a direction opposite to gravitational force, that is, of magnitude:

$$B = \rho_f V_{disp} g \quad (12)$$

where ρ_f is the density of the fluid, V_{disp} is the volume of the displaced body of liquid, and g is the gravitational acceleration at the location in question.

If this volume of liquid is replaced by a solid body of exactly the same shape, the force the liquid exerts on it must be exactly the same as above. In other words, the “buoyancy force” on a submerged body is directed in the opposite direction to gravity and is equal in magnitude to

$$B = \rho_f V g \quad (13)$$

The net force on the object must be zero if it is to be a situation of fluid statics such that Archimedes principle is applicable and is thus the sum of the buoyancy force and the object’s weight

$$F_{net} = 0 = mg - \rho_f V_{disp} g \quad (14)$$

If the buoyancy of an (unrestrained and unpowered) object exceeds its weight, it tends to rise. An object whose weight exceeds its buoyancy tends to sink. Calculation of the upwards force on a submerged object during its accelerating period cannot be done by the Archimedes principle alone; it is necessary to consider dynamics of an object involving buoyancy. Once it fully sinks to the floor of the fluid or rises to the surface and settles, Archimedes principle can be applied alone. For a floating object, only the submerged volume displaces water. For a sunken object, the entire volume displaces water, and there will be an additional force of reaction from the solid floor.

In order for Archimedes’ principle to be used alone, the object in question must be in equilibrium (the sum of the forces on the object must be zero), therefore,

$$mg = \rho_f V_{disp} g \quad (15)$$

and therefore

$$m = \rho_f V_{disp} \quad (16)$$

showing that the depth to which a floating object will sink, and the volume of fluid it will displace, is independent of the gravitational field regardless of geographic location.

(Note: If the fluid in question is seawater, it will not have the same density (ρ) at every location. For this reason, a ship may display a Plimsoll line.)

It can be the case that forces other than just buoyancy and gravity come into play. This is the case if the object is restrained or if the object sinks to the solid floor. An object which tends to float requires a tension restraint force T in order to remain fully submerged. An object which tends to sink will eventually have a normal force of constraint N exerted upon it by the solid floor. The constraint force can be tension in a spring scale measuring its weight in the fluid and is how apparent weight is defined.

If the object would otherwise float, the tension to restrain it fully submerged is:

$$T = \rho_f V g - mg \quad (17)$$

When a sinking object settles on the solid floor, it experiences a normal force of:

$$N = mg - \rho_f V g \quad (18)$$

Another possible formula for calculating buoyancy of an object is by finding the apparent weight of that particular object in the air (calculated in Newtons), and apparent weight of that object in the water (in Newtons). To find the force of buoyancy acting on the object when in air, using this particular information, this formula applies:

$$\begin{aligned} \text{Buoyancy force} = & \text{weight of object in empty space} - \\ & \text{weight of object immersed in fluid} \end{aligned} \quad (19)$$

The final result would be measured in Newtons.

Air's density is very small compared to most solids and liquids. For this reason, the weight of an object in air is approximately the same as its true weight in a vacuum. The buoyancy of air is neglected for most objects during a measurement in air because the error is usually insignificant (typically less than 0.1% except for objects of very low average density such as a balloon or light foam) (Website [2018a](#)).

Key Applications

Sea Mark Buoy

A sea mark buoy is a form of aid to navigation and pilotage that identifies the approximate position of a maritime channel, hazard, or administrative area to allow boats, ships, and seaplanes to navigate safely. Some navigational buoys are fitted with a bell or gong, which sounds when waves move the buoy. The sea mark buoy consists of a floating object that is usually anchored to a specific location on the bottom of the sea or to a submerged object.

Sea mark buoys are used to indicate channels, dangerous rocks or shoals, mooring positions, areas of speed limits, traffic separation schemes, submerged shipwrecks, and for a variety of other navigational purposes. Some are only intended to be visible in daylight (daymarks), and others have some combination of lights, reflectors, bells, horns, whistles, and radar reflectors to make them usable at night and in conditions of reduced visibility. Figure 1 shows a red sea mark buoy in San Diego Harbor, with a light, number, and radar corner reflectors (Website [2018b](#)).

Lifebuoy

A lifebuoy is a lifesaving buoy designed to be thrown to a person in the water, to provide buoyancy and prevent drowning. Some modern lifebuoys are fitted with one or more seawater-activated lights, to aid rescue at night.

The lifebuoy is usually ring- or horseshoe-shaped and has a connecting line allowing the casualty to be pulled to the rescuer in a boat. They are carried by ships and are also located beside bodies of water that have the depth or

Surface Buoy, Fig. 1 Red sea mark buoy in San Diego Harbor, with a light, number, and radar corner reflectors. (Also with a lounging sea lion.) Located at 32.69561°N 117.23099°W (Website [2018b](#))

potential to drown someone. They are often subjected to vandalism which, since the unavailability of lifebuoys could lead to death, may be punished by fines (up to £5,000 in the United Kingdom) or imprisonment. Figure 2 shows a ring-shaped lifebuoy with a light on a cruise ship (Website [2018c](#)).

The “kisby ring,” or sometimes “Kisbie ring,” is thought to be named after Thomas Kisbee (1792–1877) who was a British naval officer.

The UK Royal Life Saving Society considers lifebuoys unsuitable for use in swimming pools because throwing one into a busy pool could injure the casualty or other pool users. In these locations, lifebuoys have been superseded by devices such as the torpedo buoy.

In the United States, Coast Guard approved lifebuoys are considered Type IV personal

Surface Buoy, Fig. 2 A ring-shaped lifebuoy with a light on a cruise ship (Website 2018c)

flotation devices. At least one Type IV PFD is required on all vessels 26 feet or more in length.

Large Navigational Buoy (LNB)

A Large Navigational Buoy (LNB) is a contraction of Large Automatic Navigation Buoy. LNBs were first made in the USA by General Dynamics and adapted by Hawker Siddeley Dynamics for use in British waters in the early 1970s. The buoys were intended to replace lightships and were constructed as a circular hull with a central light to provide all-round visibility and a foghorn. They may also contain radio and radio beacons. The navigation buoy was to be monitored remotely from onshore and was designed to run for extended periods without repair. The running costs were estimated to be as little as 10% of those of a lightship.

However, experience showed that it was difficult to attain the required reliability in British waters due to the high acceleration forces experienced in rough seas with 14 m waves and 7 knot currents. Alternative experiments were made with

platforms such as the Royal Sovereign Lighthouse. The automatic technology was later used successfully in more conventional lightships. Figure 3 shows a LNB (on left) that replaced Lightship Columbia at the Columbia River Maritime Museum in Oregon (Website 2018d).

Sonobuoy

A sonobuoy is used by antisubmarine warfare aircraft to detect submarines by SONAR. It is a relatively small buoy (typically 13 cm or 5 in, in diameter and 91 cm or 3 ft. long) expendable sonar system. Sonobuoys are ejected from aircraft in canisters and deploy upon water impact. An inflatable surface float with a radio transmitter remains on the surface for communication with the aircraft, while one or more hydrophone sensors and stabilizing equipment descend below the surface to a selected depth that is variable. The specific depth depends on environmental conditions and the search pattern. The buoy relays acoustic information from its hydrophone(s) via UHF/VHF radio to operators on board the aircraft. Figure 4 shows the sonobuoy deployment procedures after impacting water (Website 2018e).

Sonobuoys are classified into three categories: active, passive, and special purpose.

Surface Marker Buoy

A surface marker buoy, SMB, or simply a blob is a buoy used by scuba divers, with a line, to indicate the diver's position to their surface safety boat while the diver is underwater. Two kinds are used: one (SMB) is towed for the whole dive and indicates the position of the dive group, and the other (DSMB) is deployed towards the end of the dive as a signal to the surface that the divers have started to ascend. Both types can also function as a depth reference for controlling speed of ascent and accurately maintaining depth at decompression stops. Figure 5 shows the picture of a typical surface marker buoy (SMB) (Website 2018f).

SMB

SMBs are floated on the surface during a dive to mark the diver's position during drift dives, night dives, mist, or disturbed sea conditions such as

Surface Buoy, Fig. 3 LNB (on left) that replaced Lightship Columbia at the Columbia River Maritime Museum in Oregon (Website [2018d](#))

Beaufort force 2 or greater. The buoy lets the dive boat follow the divers and highlights their position to other boat traffic.

Buoys for this use are usually either inflated and sealed by a valve or cap, or made from buoyant material, so they do not deflate or flood during the dive, rendering them ineffective. High-visibility colors such as red, orange, and yellow are popular. Sometimes the float includes a diving flag. If the buoy is to be towed by the diver at any speed, a low drag float and small diameter line can reduce the drag significantly.

To avoid losing the reel, a lanyard may be used to attach the diving reel to the diver. This lanyard can clip to the buoyancy compensator or go around the wrist. Alternatively, the lanyard can be long enough to float above the diver and stay out of the way. If the lanyard clips to the buoyancy compensator, the user should take care to release if there is surface boating activity, as boats may drag divers up by their SMB reels.

The DIR diving philosophy considers unsafe any attachment of the diver to equipment or objects which end above the water surface, due to high risk associated with snagging the buoy on a boat and dragging the diver upwards in spite of their decompression obligation or maximum ascent speed limit.

DSMB

A delayed surface marker buoy (DSMB), decompression buoy, or deco buoy is similar to a surface marker buoy but is deployed while the diver is submerged and generally only towards the end of the dive. The buoy marks the diver's position underwater so the boat safety cover can locate the diver even though the diver may have drifted some distance from the dive site while doing decompression stops. A reel and line connect the buoy on the surface to the diver beneath the surface. Alternative means of marking one's position while doing decompression stops are diving shots and decompression trapezes.

Surface Buoy, Fig. 4 Sonobuoy deployment procedures after impacting water (Website 2018e)

Surface Buoy, Fig. 6 Emergency wreck buoy (Website 2018g)

Surface Buoy, Fig. 5 Surface marker buoy (Website 2018f)

A closed SMB, inflated through a valve, is likely to be more reliable, by remaining inflated, than an open ended buoy which seals by holding the opening under water. A decompression buoy is not intended to be used to lift heavy weights: for this purpose divers use a lifting bag.

Emergency Wreck Buoy

An emergency wreck buoy is used to warn of a new wreck which has not yet been listed in maritime documents. The buoy is expected to be deployed for the first 24–72 h after the wreck occurs. After that time, more permanent buoyage (such as isolated danger marks or cardinal marks) should be deployed and charts updated.

The buoy is designed to provide to “provide a clear and unambiguous” mark of a new and uncharted danger. The buoy is painted with 4, 6, or 8 vertical stripes of alternate yellow and blue. In addition it may have the word “WRECK” painted on it. Optionally it may carry a vertical (St. George’s) cross painted yellow. The light flashes alternate yellow and blue for 1 s each with a half second gap between. No other navigation mark uses blue. Figure 6 shows the schematic diagram of an emergency wreck buoy (Website 2018g).

The IALA (International association of maritime aids to navigation and lighthouse authorities) defined the buoy in response to the sinking of the MV Tricolor and the subsequent collisions with the wreck by the Dutch vessel Nicola and Turkish-registered fuel carrier Vicky.

Weather Buoys

Weather buoys are instruments which collect weather and ocean data within the world's oceans, as well as aid during emergency response to chemical spills, legal proceedings, and engineering design. Moored buoys have been in use since 1951, while drifting buoys have been used since 1979. Moored buoys are connected with the ocean bottom using either chains, nylon, or buoyant polypropylene. With the decline of the weather ship, they have taken a more primary role in measuring conditions over the open seas since the 1970s. During the 1980s and 1990s, a network of buoys in the central and eastern tropical Pacific Ocean helped study the El Niño-Southern Oscillation. Moored weather buoys range from 1.5 to 12 m (5–40 ft) in diameter, while drifting buoys are smaller, with diameters of 30–40 cm (12–16 in). Drifting buoys are the dominant form of weather buoy in sheer number, with 1250 located worldwide. Wind data from buoys has smaller error than that from ships. There are differences in the values of sea surface temperature measurements between the two platforms as well, relating to the depth of the measurement and whether or not the water is heated by the ship which measures the quantity.

Weather buoys, like other types of weather stations, measure parameters such as air temperature above the ocean surface, wind speed (steady and gusting), barometric pressure, and wind direction. Since they lie in oceans and lakes, they also measure water temperature, wave height, and dominant wave period. Raw data is processed and can be logged on board the buoy and then transmitted via radio, cellular, or satellite communications to meteorological centers for use in weather forecasting and climate study. Both moored buoys and drifting buoys (drifting in the open ocean currents) are used. Fixed buoys measure the water temperature at a depth of 3 m

(9.8 ft). Many different drifting buoys exist around the world that vary in design and the location of reliable temperature sensors varies. These measurements are beamed to satellites for automated and immediate data distribution. Other than their use as a source of meteorological data, their data is used within research programs, emergency response to chemical spills, legal proceedings, and engineering design. Moored weather buoys can also act as a navigational aid, like other types of buoys.

Weather buoys range in diameter from 1.5 to 12 m (5–40 ft). Those that are placed in shallow waters are smaller in size and moored using only chains, while those in deeper waters use a combination of chains, nylon, and buoyant polypropylene. Since they do not have direct navigational significance, moored weather buoys are classed as special marks under the IALA scheme, are colored yellow, and display a yellow flashing light at night.

Discus buoys are round and moored in deep ocean locations, with a diameter of 10–12 m (33–39 ft). The aluminum 3-m (10 ft) buoy is a very rugged meteorological ocean platform that has long term survivability. The expected service life of the 3-m (10 ft) platform is in excess of 20 years and properly maintained, and these buoys have not been retired due to corrosion. The NOMAD is a unique moored aluminum environmental monitoring buoy designed for deployments in extreme conditions near the coast and across the Great Lakes. NOMADs moored off the Atlantic Canadian coast commonly experience winter storms with maximum wave heights approaching 20 m (66 ft) into the Gulf of Maine.

Drifting buoys are smaller than their moored counterparts, measuring 30–40 cm (12–16 in) in diameter. They are made of plastic or fiberglass and tend to be either bi-colored, with white on one half and another color on the other half of the float, or solidly black or blue. It measures a smaller subset of meteorological variables when compared to its moored counterpart, with a barometer measuring pressure in a tube on its top. They have a thermistor (metallic thermometer) on its base, and an underwater drogue, or sea anchor, located 15 m (49 ft) below the ocean surface connected

Surface Buoy, Fig. 7 Weather buoy operated by the National Data Buoy Center (Website 2018h)

with the buoy by a long, thin tether. A weather buoy operated by the National Data Buoy Center is shown in Fig. 7 (Website 2018h).

Spar Buoy

A spar buoy is a tall, thin buoy that floats upright in the water and is characterized by a small water plane area and a large mass. Because they tend to be stable ocean platforms, spar buoys are popular for making oceanographic measurements. Adjustment of the water plane area and the mass allows spar buoys to be tuned so they tend to not respond to wave forcing. This characteristic differentiates them from large water plane area buoys such as discus buoys that tend to be wave followers. Spar buoys are often used as stable platforms for wave measurement devices and air–sea interaction measurements. Spar buoys range in length from a few feet to the 354-foot (108 meter) RV FLIP. To avoid the difficulties inherent with shipboard launch and recovery, helicopter deployment of large spar buoys has been studied. Figure 8 is a diagram of an anchored spar buoy (Website 2018i).

Surface Buoy, Fig. 8 A diagram of an anchored spar buoy (Website 2018i)

Self-Locating Datum Marker Buoy (SLDMB)

A self-locating datum marker buoy (SLDMB) is a drifting surface buoy designed to measure surface ocean currents. The design is based on those of the Coastal Ocean Dynamics Experiment (CODE) and Davis-style oceanographic surface drifters – National Science Foundation (NSF) funded experiments exploring ocean surface currents. The SLDMB was designed for deployment by United States Coast Guard (USCG) vessels in search and rescue (SAR) missions and is equipped with a Global Positioning Satellite (GPS) sensor that, upon deployment in fresh- or saltwater, transmits its location periodically to the USCG to aid in SAR missions. Additionally, SLDMB are deployed in oceanographic research in order to

study surface currents of the ocean. This design has also been utilized by Nomis Connectivity for secure ocean-based communications.

The SLDMB is based on the Davis-style drifter design, which attempts to minimize the effects of wind and surface waves. This is accomplished by reducing the area above the ocean surface to small floats and an antenna. Below the surface is a series of drogue vanes to 70 cm (less than the 1 m Davis-style buoy) in depth, which catch the ocean current, along with electronic equipment that deploys the vanes and antenna, receives the GPS signal, and transmits the location to the USCG.

SLDMB construction varies by manufacturer, but those used by the USCG consists of four orthogonal drag vanes 0.5 m wide and 0.7 m high of nylon fabric. These are supported by PVC arms at top and bottom, which extend from a cylindrical hull that contains the electronic equipment. Small floats are attached to the end of each upper arm in order to maintain buoyancy and a small antenna projects above the SLDMB.

Deployment of the SLDMB may be accomplished by aircraft (both fixed-wing and rotary) or by ship. SLDMB deployed by aircraft are encased in a tube and attached to a parachute which decreases the impact produced upon hitting the water but without so much drag that the buoy can drift off-course according to USCG SAR guidelines. Upon reaching the ocean surface, the outer casing and parachute break away from the SLDMB, and the spring-loaded antenna deploys. Electronics consist of a GPS receiver, electronic transmitter, and sufficient batteries to provide continuous data collection for a period of 2 weeks to 1 month.

Because it has a small above-water surface and high underwater surface area, the effect of surface winds and waves has a negligible effect, instead moving with the flow of the upper 1 m of the water column. The USCG has found that this instrument behaves as a “zero-leeway” object, moving with the top meter of the water column, with no additional motion due to the direct effect of the wind on the SLDMB’s exposed areas. The USCG maintains several hundred SLDMBs for deployment and responds to more than 5,000 SAR cases each year. In the year 2006, more than 400 SLDMBs

were deployed in SAR applications, with an average lifetime of 22 days. The USCG may release SLDMBs at their discretion to aid in search efforts. In remote areas, SLDMBs are deployed via C-130 aircraft or helicopters. The GPS unit on each SLDMB calculates its position every 30 min and transmits the data via the ARGOS data collection system to USCG Operational Support Center (OSC). During high traffic periods, the USCG may predeploy units in order to have existing data in areas where SAR operations are more likely, reducing the time required to collect ocean current data during the SAR process. SLDMB may be released as single units or as a group, depending on the situation required. In cases where the last known position is known and the time lag to SLDMB deployment are minimal, only a single unit may be necessary. However, if a sufficient time lag exists, or the last known position is not available, multiple SLDMBs should be used. An example of this second case would be a downed fishing vessel, in which only the approximate area of the vessel is known (Website 2018j).

MSS – mineral storage system; MSTS – mineral storage and transport system; MTS – mineral transport system

Introduction

With the depletion of land mineral resources, the seabed mineral will become the most important resources. In order to exploit seabed resources, the world is vigorously developing deep-diving technology and deep-sea mining system (Bath 1989; Lodge and Verlaan 2018). The MSTS is the most important sea surface support system in deep-sea mining system and is an important guarantee for the seabed mineral storage and transporting to the barge (Lin et al. 2019). The MSTS has the characteristics of multiple equipment, large space, large weight and complex structure layout. The storage and transport efficiency of the system is an important indicator that directly determines whether the deep-sea mining system can continuously exploit seabed mineral (Yang et al. 2019).

The MSTS consists of two subsystems: MSS and MTS. The function of this system is to put the ores collected from the seabed into the cabin and then transfer it to the barge.

Mineral Storage and Transport System

Function

With flexible storage and transport ability, the system can properly stack and efficiently transport the pretreated ores to minimize the impact of the transport process on the stability of the mining vessel.

The storage and transport efficiency of the system should match the cutting efficiency of the seafloor mining system to guarantee the continuous operation and transport of seafloor, sea surface, and land.

The system can adapt the impact of the movement of the mining vessel itself.

Component

The MSTS consists of two subsystems: MSS and MTS. The MSS includes the cabin subdivision system and stacking system. And the MTS includes the reclaiming system, the hoisting system, and the transport system (Fig. 1).

Mineral Storage System

The cabin subdivision system transports the pretreated ores into designed cabins. Reversible belt conveyor, belt conveyor, and en masse conveyor can be used (Wang 2001).

After the ores are loaded in the cabin, the stacking plane needs to be relatively flat. Otherwise, it will cause the waste of the storage capacity around the four corners of the cabin and the imbalance of the vessel's center of gravity, which will affect the operation of the mining vessel and the safety of navigation. The stacking system mainly guarantees uniform mineral arrangement and reduces empty cabin rate. The system mainly includes throwing machine, real-time stacking monitoring system, and corresponding electronic control system.

Mineral Transport System

The reclaiming system collects ores scattered throughout the cabin and provides them to the hoisting system, which can use the double-row bucket conveyors, scraper conveyor, bucket elevator, and so on (China Heavy Machinery Industry Association 2015).

Surface Mineral Storage and Dump, Fig. 1 Components of the MSTs

The hoisting system lifts the ores from the cabin to the height that can be transported to the side of the vessel. The commonly used lifting methods include belt conveyor and mechanical type. Belt conveyor mainly includes inclined belt conveyor, C belt conveyor, waving belt conveyor, and so on. Mechanical hoisting type mainly includes bucket elevator, screw conveyor, bucket wheel machine, grab crane, and so on.

The transport system transports mineral that is hoisted to a certain height to the barge. The common equipment includes the telescopic loading machine, shuttle conveyor, and so on. The telescopic loading machine is composed of the boom belt conveyor, transition belt conveyor, telescopic barrel, pitching device, rotary device, and etc. Shuttle belt conveyor

developed on the basis of DTII(A) belt conveyor is a kind of mobile belt conveyor with running wheels.

Basic Procedure

The ores collected on the seabed is transported to the sea surface by the seafloor mining system and then processed by the mineral pretreatment system. The cabin subdivision systems, according to ship loading requirements, deliver ores to different cabins. The ores are distributed reasonably and evenly in the cabins with the stacking system. When the cargo hold is almost filled with ores, the reclaiming system collect the ores and lift them to the deck level through the hoisting system. Finally, with the help of the transport system, these ores are transported to the barge. The MSTs

Surface Mineral Storage and Dump, Fig. 2 Basic procedure of the MST

provides efficient storage and transports to ensure continuous operation of the deep-sea mining system as well as continuous transport of seabed mineral to the land (Fig. 2).

Definition

The surface warships are a kind of naval vessels, which are usually equipped with a certain number of soldiers, weapons, and special equipment and mainly sail on the surface of water with tactical and technical capabilities required by warfare or service support missions.

Scientific Fundamentals

Historic Evolution of Surface Warships

From ancient times, ships have been extremely important transportation vehicles and military weapons. During the Stone Age, ancient humans waded through canoes and rafts to carry out fishing and hunting. With the development of technology, the ancient humans created sails and oars to control navigation of ships, and wooden sailing warships began to dominate the sea from then on. Since the modern industrial revolution,

especially after the application of welding technology and steel materials, the performance of ships has been greatly enhanced (Marshall 1995; Gibbons 2001).

In the long period of feudalism, wooden sailing warships had been dominant control by naval forces. Since the mid-fourteenth century, sailing warships had gradually been equipped with artillery on both sides; by the seventeenth century, the tactics of ship-to-ship gunnery had developed into the main tactics of naval warfare; during the eighteenth century, the naval fleets gunnery tactic had further developed into the stable and well-known “line-of-battle” tactic (Konstam and Bryan 2001). At that time, the warships with large tonnage and heavy artillery were directly responsible for the combat mission of the “line-of-battle” tactics, which was later known as battleships.

At the beginning of the nineteenth century, steam engine technology and metal smelting technology made great progress, which resulted in a greater breakthrough of modern shipbuilding industry, thus contributing to the profound significance of the warships.

In the Battle of Sinop during the Ceimean in 1853, General Nakhimov of Russia Navy commanded the Black Sea Fleet performing ingenious tactic and newly assembled blasting cannons to annihilate the sailing warships of Turkish Navy. In the later period of the naval warfare, the advanced steam-powered warships of both Britain and France perfectly demonstrated the advantages of maneuverability, and finally sailing warships lost the dominant position of naval warfare (Badem 2010). The Crimean War ended in 1856, and formally established the important dominance of steam-powered warships in naval fleets and maritime warfare, and prompted the development of warships toward the direction of armor.

At the early twentieth century, the British “HMS Dreadnought” was launched into service. The “HMS Dreadnought,” completely equipped with large-caliber artillery, was the first warship to be driven by a steam turbine, and the world’s most advanced and largest battleship at that time (Fairbanks 1991). The armored “Dreadnought” had dominated the world navies for 40 years, marking the arrival era of brilliant “Big-ship,

Big-gun” (Robert 1992). As a result, arms races spread around the world. In 1916, the Battle of Jutland made the glory of “Dreadnought” reach its peak; the world navies began to manufacture giant battleships equipped with large-caliber artillery (Black 2016).

The main types of surface warships at different times are shown in Fig. 1. After World War II, with the rapid development of modern science and technology, the industrial automation of shipbuilding has been increasingly improved, as well as the quality and manufacturing efficiency. Moreover, with the carrier-based weapons, power plants, shipbuilding materials, electronic equipment, and shipbuilding processes booming, the development of surface warships steps into modernization.

Main Types and Characterizations of Modern Surface Warships

Surface warships are the oldest type of naval vessels, so it can be said that without surface warships, there would be no naval fleets. At present, according to different missions undertaken by surface warships, they can be generally classified into combat warships and auxiliary warships.

The Battleship

The battleship is a kind of large-scale surface combat ship with large-caliber artillery as main weapon and heavy armored protection, and also capable of carrying out ocean-going combat missions. Battleships used to be the capital ships of navy fleets, and are generally divided into single column as “line-of-battle” tactic for artillery battles (Lavery 1983). The battleship was also known as Ironclad or Panzership at early times.

From the late nineteenth century to the early twentieth century, the battleship was considered to be the most powerful warships, and have always been one of the capital ships in major maritime powers. The most prominent feature of battleship is a great number of large caliber guns, and the maximum diameter of a single gun can reach 460 mm. What’s more, the maximum thickness of armors is at least the same as main gun caliber, and the displacement can reach 50,000~60,000 tons, with once endurance ranging from 10,000 to 15,000 miles. After World War II,

▲ Santisima Trinidad. The most spectacular battleship of the entire sail era—the only four-story artillery deck battleship during the 18th century.

▼ KM Bismarck Battleship. Served in Nazi Germany in 1940, one of the largest and most technologically advanced battleships during World War II.

▼ USS Long Beach. The world's first nuclear-powered guided missile cruiser, served in the United States Navy in 1961.

► HMS Dreadnought. Served in the British Royal Navy in 1906, and was the first main warship powered by steam turbines during the history of modern navy.

▼ USS Enterprise. The world's first nuclear-powered aircraft carrier, served in the United States Navy in 1961.

◀ DING YUAN Ironclad. Served in the BeiYang Fleet of Qing Dynasty in 1885, and was the largest warship in the Far East during the time.

▼ Horizon-class Destroyer. A class of air-defence destroyers in service with the French Navy and the Italian Navy in 2008.

◀ Type 23 Frigate. Served in 1990, as a large ocean-going multipurpose frigate under the British Royal Navy.

Surface Warships, Fig. 1 Main types of surface warships at different times (<https://en.wikipedia.org/>)

the strategic dominance of battleship was gradually replaced by aircraft carrier and ballistic missile submarine.

As shown in Fig. 2, the US “Iowa-class” battleship was latest decommissioned, and also the largest tonnage built by the US navy during World War II. There are a total of four “Iowa-class” battleships built since 1940, namely “Iowa”(BB-64), “New Jersey”(BB-62), “Missouri”(BB-63), and “Wisconsin”(BB-64). The hull length of “Iowa-class” is 270.4 m with 33 m in width, 11.6 m in draught, and a standard displacement of 45,000 tons. The whole ship was equipped with armor protection, as the thickness

of common parts is 150 mm and important parts can reach 400 mm, which was the thickest armored surface warship in the world after the war (Burr and Bull 2010). During World War II, the “Iowa-class” battleships successively participated in the Battle of Marshall Islands, the Battle of Marianas, the Battle of Okinawa, etc.

The Cruiser

The cruiser is a kind of large-scale surface combat ship with a displacement of more than 7,000 tons, equipped with guided missiles, naval guns, and carrier-based helicopters. Cruisers are a kind of relatively old navy warships, which

Surface Warships, Fig. 2 Iowa fires during a target exercise near Vieques Island (<http://ww2db.com/>)

Kirov-class Battlecruiser "Pyotr Velikiy"

Ticonderoga-class Cruiser "Normandy"

Surface Warships, Fig. 3 Typical cruiser in active service (<https://en.wikipedia.org/>)

almost were born and developed at the same time as battleships. Cruiser has the characteristics of high speed, great endurance, and better sea-keeping, which can make a contribution to carrying out ocean-going combat missions a long time in atrocious weather. The main weapons of the early cruisers were the artillery, once known as artillery cruiser, but then replaced by missile cruiser. In the twenty-first century, cruisers are basically no longer built, which may gradually be replaced by destroyers.

At present (as of April 2018), there still are 15 "Ticonderoga-class" cruisers in active

service of the US Navy, all of which are conventional-power missile cruisers; Russia's active cruisers include two nuclear-powered "Kirov-class" battlecruiser, three conventional-powered "Slava-class" cruisers. Fig. 3 shows the active "Peter the Great" nuclear cruiser and the "Normandy"-guided missile cruiser.

The "Kirov-class" battlecruiser was developed by the former Soviet Union in the early 1980s. A total of four "Kirov-class" cruisers were built, and there are still two cruisers serving in the Russian Northern Fleet presently. The "Kirov" (original name) is the first battlecruiser of this

class with a plump shape, and adopting with an outboard bow, a large square stern, and flight deck. The “Kirov” is 250.1 m in length, 28.5 m in width, with a maximum speed of 31 knots, full displacement of 28,000 tons, and a crew of 900. The “Kirov” began to take service in July 1980 that was the largest cruiser built after World War II (Pair 2011).

The Destroyer

The destroyer is a kind of medium-scale surface combat ship mainly equipped with guide missiles, naval guns, and anti-submarine weapons with multiple battle capabilities, which has been a kind of important naval warships since the nineteenth century. Modern destroyers can be mainly classified into the anti-aircraft destroyers and the anti-submarine destroyers.

The displacement of anti-aircraft destroyers is generally between 6,000 and 10,000 tons, with the main missions of fleet air defense (FAD); likewise there is a trend of further large-scale development, such as the US Navy latest “Zumwalt-class” with full-load displacement reaching 15,000 tons. The anti-aircraft destroyers are mainly equipped with a set of phased array radars, long-range ship-to-air guided missiles, and high-performance automated command system, as well as naval guns, short-range defense systems, anti-submarine deep-water bombs, and torpedoes. There are typical anti-aircraft destroyers such as the US “Arleigh Burke-class” destroyer, the “Type 055” destroyer of China, and the European “Horizon-class” destroyer.

The displacement of anti-submarine destroyers is generally between 3,000 to 6,000 tons, with the main combat missions of anti-submarine and anti-ship warfare. The anti-submarine destroyers are mainly equipped with sophisticated sonar anti-submarine system and anti-ship weapons, at the same time, by means of short-range missiles to assist anti-aircraft operations. There are typical anti-submarine destroyers such as the Russian “Udaloy-class” destroyer, the US “Spruance-class” destroyer, and Japanese “Hatakaze-class” destroyer.

The “Type 055” destroyer is a class of guided missile destroyer being constructed for Chinese

People’s Liberation Army Navy, and also is a multi-mission design aimed to undertake expeditionary missions and form the primary escort for the aircraft carriers of Chinese Navy. The “Type 055” adopts a conventional flared hull with distinctive stealthy features including an enclosed bulbous bow which can hide mooring points, anchor chains and other equipment, in addition, the bow and main deckhouse are configured similarly to previous “Type 052D”. The full-load displacement of “Type 055” is about 12~13,000 tons, with a length of 180 m and maximum service speed reaching 30 knots. Fig. 4 demonstrates the sea trial of the first “Type 055” destroyer. The first ship of “Type 055” launched on 28 June 2017, which indicated that “Type 055” was the largest post-Second World War warships in East Asia.

The Frigate

The frigate is a kind of light-scale surface combat ship that is mainly equipped with guided missiles, naval guns, deepwater bombs, and anti-submarine torpedoes. The frigates originated from a three-mast armed sailing ship in sixteenth century, and are a kind of traditional naval warships, which are also a type of surface warships with the largest number, the most extensive distribution, and the most opportunities for warfare in major coastal countries. Frigates are mainly applied for anti-submarine, sea escort, reconnaissance, mine-laying, and support landing operations.

Surface Warships, Fig. 4 Sea trial of the first “Type 055” destroyer (<http://www.guancha.cn/>).

There are more than 50 countries and regions owning frigates all over the world. According to the difference of displacement and operational environment, the frigate can be classified into offshore frigate and ocean-going frigate. The offshore frigates typically include the South Korean “Pohang-class” corvette and the Chinese “type-056” frigate. The ocean-going frigates typically include the US “Oliver Hazard Perry-class” frigate, the British “Duke-class” frigate, and the Russian “Neustrashimyy-class” frigate.

The “Oliver Hazard Perry-class” frigate is a kind of ocean-going frigates with moderate performance of the US Navy. The “Perry-class” frigates have a variety of tactical roles and can undertake various missions which are one of the most advanced missile frigates. The “Perry-class” frigate is 135.6 m in length, 13.7 m in width, 6.7 m deep in draft, and a full-load displacement of 3,600 tons, with a speed of 30 knots. In addition, the “Perry-class” frigates also are exported to nearly 10 countries and regions in the world (Zhang 2015). Fig. 5 shows that the “Ford” of “Perry-class” was performing a cruise mission. In September 2015, the last frigate of the “Perry-class” “Kauffman” (FFG-59) was decommissioned, marking the complete decommission of the “Perry-class”.

The Aircraft Carrier

The aircraft carrier is a kind of large-scale surface warship with carrier-based aircrafts as main weapons, which is usually equipped with a huge full-length flight deck and island located on the starboard side. The aircraft carrier is the capital ship of a navy fleet, mainly responsible for air supports and long-range strikes, and other warships of the fleet are responsible for providing protection and supply. So far, the aircraft carrier has been one of the largest, most complex and powerful weapons in the world. Moreover, the aircraft carrier has become indispensable for the modern navy, and also been a symbol of comprehensive national strength.

Modern aircraft carriers are usually classified into large-scale aircraft carriers (over 60,000 tons), medium-scale aircraft carriers (about 30,000 to 60,000 tons), and light-scale aircraft carriers (below 30,000 tons), according to the bulk of full-load displacement. In addition, according to the different type of power-plants, aircraft carriers can also be classified into nuclear powered aircraft carriers and conventional power aircraft carriers. At present, only eight countries possess aircraft carriers, but only the US “Nimitz-class,” “Ford-class,” and French “De Gaulle-class” are currently equipped with nuclear-power, and the rest are conventional-power aircraft carriers.

Perry-class frigate
“Ford” (<http://www.navsource.org/>)

Surface Warships,

Fig. 6 Type 001 Aircraft Carrier “Liaoning” (<http://www.haijun360.com/>)

The Chinese “type 001” aircraft carrier “Liaoning” is the first aircraft carrier of the PLA navy, whose predecessor was the Soviet navy “Kuznetsov-class” aircraft carrier “Varyag.” In 2005, the uncompleted aircraft carrier was modified and reconstructed for scientific research, experiment, and training. In September 2012, the “Varyag” was renamed as “Liaoning,” and was delivered to the PLA navy. Fig. 6 demonstrates the sea trials of “Liaoning.” At present, the “Type 001A” aircraft carrier designed and constructed autonomously by China was launched on April 26, 2017.

The Landing Craft

The surface landing craft is a kind of warship that mainly transports landing soldiers, replenishments, military weapons, and performs landing frontages. Landing frontages are always the most difficult in naval warfare, and the landing forces would receive fire supports from the air and sea, in order to ensure that landing crafts can safely transport soldiers and equipment to the coast. Landing crafts can be classified into amphibious warfare ship (such as LPH/LHA/LHD), dock landing ship (LSD), amphibious cargo ship (such as LKA), and light landing craft (such as LCU/LCM/LCAC), amphibious command ship (such as LCC/AGF), depending

on different missions undertaken at warfare. So far, most countries have strengthened the development of landing crafts, and many landing crafts have both plane landing and vertical landing capabilities.

The amphibious assault ship is a kind of landing craft that can provide air and surface supports behind the battlefield when conducting amphibious operations in hostile coastal areas. This type of landing craft was developed from Landing Helicopter Dock, but also combines with the well deck design, which can be used to load landing boats, transport tanks, and provides take-off and landing environment for carrier-based aircraft (Friedman 2002). The US active “Wasp-class” amphibious assault ship is currently the largest multifunctional amphibious assault ship in the world, with a full-load displacement of 41,150 tons. Fig. 7 shows the “Wasp-class” amphibious assault ship “Makin Island.” The “Wasp-class” can carry almost a whole US Marine Corps unit and campaign at the battlefield of hostile territory through helicopters and other landing crafts.

The Hospital Ship

The hospital ship is a kind of special auxiliary warship that combines rescue and wounded

Surface Warships,

Fig. 7 Wasp-class Amphibious Assault Ship “Makin Island” (<http://www.navsource.org/>)

**Surface Warships,**

Fig. 8 Peace Ark Hospital Ship “Daishan Dao” (<http://www.haijun360.com/>)

evacuation on the ocean, and is equipped with medical treatment staff, departments and medical equipment, a large number of relatively advanced rescue and evacuation facilities, known as the “marine hospital.” Large-scale hospital ships are one of the important symbols of the modern navy, and there are a few countries in the world, such as the United States, Britain, Canada, and China, which possess hospital ships with capacity to provide medical assistance away from the land.

“Peace Ark” is a professional large-scale hospital ship designed for maritime medical treatment in China. The original name is “Daishan Dao,” with a full-load displacement of 14,300 tons, which is equipped with nearly 2400

sets of advanced medical equipment and more than 500 beds. Fig. 8 shows the hospital ship “Peace Ark.” The “Peace Ark” is the world first large-scale professional hospital ship of 10,000 tons, which formally commissioned in the East Sea Fleet at the end of 2008, and has carried out humanitarian medical treatment many times and “Rim Pacific” military exercises.

The Replenishment Ship

Replenishment ships are a kind of auxiliary warships that are used to provide military supplies such as fuel, ammunition, food, and attachments for aircraft carrier fleets, or warships. The replenishment ships were widely used at the Pacific

Surface Warships, Fig. 9 Sacramento-class fast combat support ship “Camden” (<http://www.globalsecurity.org/>)

battlefield during World War II. The modern replenishment ships are equipped with advanced remote-maintenance system, which are main logistics supports for military activities in the ocean.

The US “Sacramento-class” fast combat support ship was the first class of integrated replenishment ships in the world, and the first ship “Sacramento” (AOE-1) was built in the 1960s. So far, she has been still the largest and fast integrated replenishment ship of the world. Fig. 9 shows the “Sacramento-class” fast combat support ship “Camden.” The main missions of “-Sacramento-class” are to accompany the aircraft carrier fleets to provide supplies. The “Sacramento-class” can carry 177,000 barrels of fuel, 2,150 tons of ammunition, and 7,500 tons of dry-cold cargo. What’s more, she also has 15 refueling stations, and is usually equipped with three “UH-46” helicopters for vertical replenishment, enabling the fleet sail away from the base for a long time to maintain battle activities. Up to now, the “Sacramento-class” fast combat support ships have all decommissioned.

Key Applications

Advanced Large-Scale Aircraft Carriers of Maritime Power

As the most powerful maritime military power in the world, the US Navy has as many as 11 aircraft carriers in active service (10 for the “Nimitz-

class” and 1 for the “Ford-class”), and all belong to large-scale aircraft carriers with full-load displacement over 100,000 tons. The “Nimitz-class” aircraft carriers are current main forces of the ocean-going navy fleets, and are also the second-generation of US nuclear-powered aircraft carriers succeeded from the “Enterprise” aircraft carrier. The “Nimitz-class” aircraft carrier CVN-68 is shown in Fig. 10.

The “Ford-class” aircraft carrier started to be built in August 2005, and took active service in July 2017. The first sea trial of “Ford-class” CVN78 in 2017 is shown in Fig. 10. The “Ford-class” is the current largest nuclear-powered aircraft carrier of the US Navy, with a maximum speed of over 30 knots and also the first carrier to adopt electromagnetic launching system.

Lost Battleship During World War II

The Japanese “Yamato-class” battleship used to be the largest one in the world, with a standard displacement of 64,000 tons, and a full-load displacement of nearly 73,000 tons, more than 20 large-caliber main and auxiliary guns, and a speed of 27 knots (Taylor 2017). The first ship “Yamato” began serving in the Imperial Japanese Navy in 1941 and was once known as “the world first battleship.” Fig. 11 shows the trial of the Yamato. Unfortunately, during the battle of Okinawa on April 7, 1945, Yamato was attacked by waves and waves of American carrier planes. She received serious damage from falling bombs

Nimitz-class "CVN-68"

Ford-class "CVN78"

Surface Warships, Fig. 10 Nimitz-class and Ford-class Aircraft Carrier (<http://www.maritimequest.com/>)

Surface Warships, Fig. 11 Yamato on trials in Sukumo Bay, October 30, 1941 (<http://battleshiplist.com/>)

within the first 15 min of the battle, then was struck by torpedoes on the port side. The largest battleship in the world finally sank, after an agonizing for 2 h.

The Active Destroyers of US Navy

The US Navy destroyers in active service include the "Arleigh Burke-class" and the "Zumwalt-class." The characteristics and configuration parameters of the two types of warships are shown in Fig. 12.

The "Arleigh Burke-class" is a kind of primary air defense guided missile destroyer, and also the world's first destroyer equipped with the "Aegis" system and completely adopting a stealth shaping design (Zhou et al. 2003).

The "Arleigh Burke-class" destroyer adopts a wide-short shaped type of single hull, with a V-shaped profile at the bow, a clear outboard above the waterline, and an inward slope on the side, which can greatly improve the seakeeping. In order to improve the vitality of the warships, the tactical operations centers are all in the main hull, and important cabins are fully equipped with "KEVLAR" armors, with full considerations given to the measurements to reduce damages and maintain combat effectiveness.

The "Zumwalt-class" destroyer is the new generation for multi-mission Aegis warships. This class of destroyers from the ship hull design, pipeline communication, network communication and motor power, weapon

Arleigh Burke-class "DDG-51"

Zumwalt-class "DDG- 1000"

Surface Warships, Fig. 12 US navy active destroyers (<http://www.navsourc.org/>)

Surface Warships, Fig. 13 Zubr air-cushioned landing craft (<http://mil.ru/>)

systems are beyond the cutting edge of modern technology (Xiong et al. 2016). The “Zumwalt” is the first destroyer of this class, and began to formally active service in October 2016. The hull of “Zumalt” is 182 m long which is 1.5 times longer than the “Arleigh Burke-class” destroyers, and a full-load displacement of 15,000 tons, ranked as the largest and most advanced destroyer of the US Navy.

Amphibious Warfare Pioneers of offshore Landing Crafts

The light landing craft is a kind of small-scale amphibious ship that is specifically developed for the transport of landing soldiers, weapons and landing supplies. The landing craft first appeared before the World War II and played an important role during the Normandy Landing

campaign. The European “Zubr” is the largest air-cushioned landing craft in the world, and is mainly used to perform offshore amphibious campaign in a confined sea area. Fig. 13 shows the “Zubr” air-cushioned landing craft, of which the full-load displacement is 555 tons, with a maximum speed of 63 knots, and an endurance of 300 miles at average speed of 55 knots.

[Broaching](#); [Broaching stability](#)

Definition

Broaching is a violent uncontrollable turn that occurs despite maximum steering efforts to maintain the course. As with any other sharp turn event, broaching is accompanied with a large heel angle, which has the potential effect of a partial or total stability failure. Broaching is usually preceded by surf-riding which occurs when a wave, approaching from the stern, captures a ship

and accelerates the ship to the speed of the wave. Surf-riding is a single wave event in which the wave profile does not vary relative to the ship. Because most ships are directionally unstable in the surf-riding condition, this maneuvering yaw instability leads to an uncontrollable turn – termed “broaching” (IMO 2016). Broaching is considered as one of the most dangerous phenomena in following and stern-quartering waves for high-speed ships, such as destroyers and fishing vessels.

When a ship proceeds in following waves, three main forces act in the axial direction. Thrust is the force produced by the ship's propulsor to propel the ship forward. Resistance is the force that opposes the forward ship motion. The surging wave force is the force imparted by a wave to either push the ship forward or back depending on whether the ship is on the face or back of a wave, respectively. These forces are represented in Fig. 1 (IMO 2016).

When a surging wave force is present, three conditions are possible: surging motion, surf-riding under certain initial condition, and surf-riding under any initial condition.

Surging motion. This condition occurs when the wave surge force is insufficient to overcome the difference between the thrust of the ship's propulsor and the resistance of the ship at the wave celerity. In this case, the ship oscillates from increasing speed when on the front side of the wave to decreasing speed when on the back side of the wave (IMO 2016).

Surf-riding under certain initial condition (first threshold of surf-riding). This condition occurs is the ship speed for which the forward surge force of the wave at a particular point on the wave can exceed the difference between the thrust of the ship's propulsor and the resistance of the ship at the wave celerity. In this case, surf-riding could occur if the ship is accelerated with some external force under the self-propelled condition (IMO 2016).

Surf-riding under any initial condition (second threshold of surf-riding). This is the situation for which the ship kinetic energy is too large for the ship to be overtaken by a wave. Thus, the oscillatory surge motion cannot stably exist that surf-

Surf-Riding and Broaching, Fig. 1 Forces acting on a ship in following waves (Belenky et al. 2011; IMO 2016)

riding occurs regardless the initial ship position and forward speed (IMO 2016).

The resistance curve is approximated using the following polynomial expression with respect to ship speed u :

Scientific Fundamentals

The Generalized Expression for an Approximated Surge

The equation representing nonlinear surge motion is described as follows:

$$(m + m_x)\ddot{\xi}_G + [R(u) - T_e(u, n)] - X_w = 0 \quad (1)$$

where the overdot denotes differentiation with respect to time t . Here, R the ship resistance, T_e the propeller thrust, m the ship mass, m_x the added mass in x direction, u the ship forward velocity, and n the propeller revolution rate (RPM).

Assuming that the hull form is almost longitudinally symmetric, the Froude-Krylov force is represented as a first-order approximation and takes a form as follows:

$$X_w \approx -f \sin(k\xi_G) \quad (2)$$

$$f = \rho g k \frac{H}{2} \mu_x \sqrt{F_C^2 + F_S^2} \quad (3)$$

where the wavenumber k is defined as $2\pi/\lambda$, and λ is the wavelength. f is the exited wave force in the surge direction. H is the wave height. F_C and F_S is the real part and the image part of the Froude-Krylov. μ_x is the coefficient considering the effect of diffraction force.

$$R(u) = \sum_{i=0}^N r_i u^i = r_1 u + r_2 u^2 + \dots \quad (4)$$

where, $r_i (i = 0, 1, 2, \dots)$ is a polynomial fit of the resistance coefficient curves, and $r_0 = 0$.

The ship thrust is represented by the following quadratic expression:

$$T_e(u, n) = (1 - t_p) \rho n^2 D^4 K_T(J) \quad (5)$$

$$K_T(J) \approx \sum_{i=0}^N \kappa_i J^i = \kappa_0 + \kappa_1 J + \kappa_2 J^2 + \dots \quad (6)$$

$$J = \frac{u(1 - w_p)}{nD} \quad (7)$$

where κ_i is a polynomial fit of the thrust coefficient curves. In these equations, t_p and w_p are the thrust deduction and wake fraction, respectively. These are taken at their still water values. Here D and ρ are the propeller diameter and water density.

The effective propeller thrust in still water can then be expressed as:

$$T_e(u, n) = \sum_{i=0}^N \frac{(1 - t_p)(1 - w_p)^i \rho \kappa_i u^i}{n^{i-2} D^{i-4}} \quad (8)$$

Substituting Eqs. (2), (3), (4), (5), (6), (7), and (8) into Eq. (1), here the relative velocity $\dot{\xi}_G = u - c_w$, replacing u with $\dot{\xi}_G$ and c_w , the following equation is obtained:

$$\begin{aligned} (m + m_x)\ddot{\xi}_G + \sum_{i=1}^N \sum_{j=1}^i c_i \binom{i}{j} \dot{\xi}_G^j c_w^{i-j} \\ + f \sin(k\xi_G) \\ = T_e(c_w; n) - R(c_w) \end{aligned} \quad (9)$$

where the coefficients c_i are defined as

$$c_i \equiv -\frac{(1-t_p)(1-w_p)^i \rho k_i}{n^{i-2} D^{i-4}} + r_i; \quad (10)$$

Here c_w is the wave celerity.

Melnikov's Method for Obtaining the Generalized Expression for an Approximated Surge

Melnikov's method is one of the usual analytical approaches, and this technique is applied in this context referring (Maki et al. 2010; Maki et al. 2016).

Putting $y = k\xi_G$, and $\tau = t\sqrt{fk/(m+m_x)}$ in Eq. (9) yields the following equation:

$$\begin{aligned} \ddot{y} + \sum_{i=1}^N \sum_{j=1}^i C_{ij} \dot{y}^j + \sin y \\ = \frac{T_e(c_w; n) - R(c_w)}{f} \end{aligned} \quad (11)$$

$$C_{ij} \equiv \frac{c_i}{fk^j} \binom{i}{j} \frac{(fk)^{j/2}}{(m+m_x)^{j/2}} c_w^{i-j} \quad (12)$$

Putting ε which is $0 < \varepsilon \ll 1$ in Eq. (11) yields the following equation:

$$\ddot{y} + \sin y = \varepsilon \left(\frac{T_e(c_w; n) - R(c_w)}{f} - \sum_{i=1}^N \sum_{j=1}^i C_{ij} \dot{y}^j \right) \quad (13)$$

When $\varepsilon = 0$, the Hamiltonian part of Eq. (13) is:

$$\ddot{y} + \sin y = 0 \quad (14)$$

Putting $y = y$ and $z = \dot{y}$ in Eq. (14) yields the following equation:

$$\begin{cases} \dot{y} = z \\ \dot{z} = -\sin y \end{cases} \quad (15)$$

Equation (15) is also a Hamiltonian system, and the flowing equation can be used:

$$H(y, z) = \frac{z^2}{2} - \cos y \quad (16)$$

Putting $\dot{y} = 0$, $\dot{z} = 0$ in Eq. (15) yields the following equation:

$$\begin{cases} \dot{y} = z = 0 \\ \dot{z} = -\sin y = 0 \end{cases} \quad (17)$$

Three stable points (0,0), $(\pm\pi, 0)$ can be obtained by Eq. (17). $(\pm\pi, 0)$ are saddle points and (0,0) is the center.

When $H(\pm\pi, 0) = 1$, heteroclinic trajectory connecting the saddle points $(\pm\pi, 0)$ is as following:

$$H(\pm\pi, 0) = \frac{z^2}{2} - \cos y = 1 \quad (18)$$

$$z = \pm\sqrt{2(1 + \cos y)} = \pm 2 \cos(y/2) \quad (19)$$

where “+” is the upper part and “−” is the lower side of the heteroclinic trajectory.

The heteroclinic trajectory is shown in Fig. 2. The point is close to the saddle points A and B when $\tau \rightarrow +\infty$ and $\tau \rightarrow -\infty$.

The heteroclinic trajectory is the boundary of surf-riding and stable motion, and the two saddle points is the balance points of surf-riding. There is heteroclinic trajectory for the balance point A to balance point B after a long time and is called heteroclinic bifurcation.

So the trajectory connecting the two saddle points $(\pm\pi, 0)$ on the lower side of vector field can be determined as follows:

$$z = \dot{y} = -2 \cos(y/2) \quad (20)$$

Here, the Melnikov function is defined as follows:

Surf-Riding and Broaching, Fig. 2 The heteroclinic trajectory

$$M = \int_{-\infty}^{+\infty} z \left(\frac{T_e(c_w; n) - R(c_w)}{f} - \sum_{i=1}^N \sum_{j=1}^i C_{ij} \dot{y}^j \right) d\tau \quad (21)$$

Substituting Eq. (20) into Eq. (21) and changing variables yield:

$$\begin{aligned} M &= \int_{-\infty}^{+\infty} \frac{T_e(c_w; n) - R(c_w)}{f} \frac{dy}{d\tau} d\tau \\ &- \sum_{i=1}^N \sum_{j=1}^i C_{ij} \int_{-\infty}^{+\infty} \dot{y}^j \frac{dy}{d\tau} d\tau \\ &= - \int_{-\pi}^{\pi} \frac{T_e(c_w; n) - R(c_w)}{f} dy + \sum_{i=1}^N \\ &\times \sum_{j=1}^i C_{ij} \int_{-\pi}^{\pi} \dot{y}^j dy \end{aligned} \quad (22)$$

Assuming that $M = 0$, the following relationship can be obtained:

$$\begin{aligned} 2\pi \frac{T_e(c_w; n) - R(c_w)}{f} \\ = \sum_{i=1}^N \sum_{j=1}^i C_{ij} (-2)^j I_j \end{aligned} \quad (23)$$

$$I_j = \int_{-\pi}^{\pi} \cos^j(y/2) dy \quad (24)$$

Equation (23) is the approximated condition for the surf-riding threshold. Critical revolution

n_{cr} can be obtained by Eq. (22), and then critical ship forward speed u_{cr} and Fn_{cr} can be obtained by the following equation.

$$T_e(u_{cr}; n_{cr}) - R(u_{cr}) = 0 \quad (25)$$

Key Applications

The first example is the ITTC ship A-2 whose principal particulars are given in Table 1. The calculated results of the surf-riding threshold using Melnikov method are shown in Fig. 3.

The second example is about the ONR tumblehome vessel. The free running experiment of the ONR tumblehome vessel was conducted to recur the surf-riding and broaching phenomena in regular following and stern-quartering waves at the maneuvering and seakeeping basin of China Ship Scientific Research Center (CSSRC). The basin is 69 m length, 46 m breadth, and 4 m depth, which is equipped with flap wave makers at the two adjacent sides of the basin. The ship

model was equipped with double propellers and double rudders. Ship motions were measured by the MEMS (Micro Electro-Mechanical System)-based gyroscope placed on the ship model.

The principal particulars of the ONR tumblehome vessel are shown in Table 2. The ship model in free running experiment is shown Figs. 4 and 5.

As shown in Figs. 4 and 5, the ship experiences surf-riding and broaching in two wave conditions, respectively. Surf-riding and broaching often occur on the down slope of a wave, and broaching always accompanied with a large heel angle,

Surf-Riding and Broaching, Fig. 5 A snapshot of broaching in the experiment

which may lead to stability failure, or even capsizing.

The experiment results in following waves are shown in Figs. 6 and 7. The pitch motion of the ship appears periodic at the beginning, and then the amplitude of pitch motion is almost unchanged in later time. While yaw motion is generally small all the time. It reveals that the ship experiences stable surf-riding.

With the wave steepness increasing and the heading changing to stern-quartering waves as shown in Figs. 8 and 9, the ship surf-riding occurs quickly. Then the ship cannot keep its course even with maximum steering effort, and broaching occurs. At the same time, roll angle is increasing fast. But with the action of rudders, the ship is stable at a new heading temporarily. And then the ship is captured again by a new wave and surf-riding and broaching occur once more. At the

Definition

Taut mooring, as a new type of mooring systems for deepwater operation platforms, maintains taut condition by applying pretension on both ends of the cable. The composition materials tend to choose the combination form of the chain-

polyester-chain to meet the needs of deep-sea work. It has been widely used due to its small mooring radius, low total mass, and good corrosion resistance.

Introduction

With the increasing scarcity of oil and gas resources on land and in the shallow sea, development toward the deep sea has become an inevitable trend. But the harsh environment on the ocean and the positioning requirements of the deep-sea drilling platform have made the research, design, and manufacture of the deep-sea marine structure mooring system face new challenges and once became the technical bottleneck of deep-sea oil and gas exploration. In recent years, research and development of new mooring methods and mooring materials have made great progress, from the traditional catenary mooring system to the deep-sea drilling platform, such as the taut mooring system (Fig. 1) adopted by Spar and TLP platforms. Traditional large-mass anchor chains and steel cables are increasingly unable to meet the needs of deep-sea drilling and development. With the increased depth of the floating structure operation, the chain will be a rapid increase in weight, not only increases the tension in the chain, and increased by the vertical load of the floating structure, such that the payload further floating structure can have the reduction. In addition, with the increase

Taut Mooring, Fig. 1 Taut mooring system of a semi-submersible platform. (From anchor manual 2005)

of water depth, positioning capabilities of chain mooring system will decline rapidly. Thus, deep-water mooring system for floating marine structures often uses taut mooring.

Composition Materials

The taut mooring system was developed with the application of fiber materials to the deep sea and was first applied to the tension leg platform and the Spar platform in the 1980s. It fixes the platform directly to the sea floor through mooring cables. The middle part of the mooring cable is mostly made of light-weight high-strength nylon rope, polyester rope or other synthetic materials, and wear-resistant steel anchor chains at both ends of the cable or wire rope (Fig. 2). Synthetic fiber ropes are usually made of PET, HMPE, Aramid, etc., of which polyester fiber is the most widely used. By comparison, these materials used in taut mooring systems have a larger strength-mass ratio to mitigate the loss of vessel effective payload, low axial stiffness to facilitate the rope elongation to adapt the vessel offset, obviously shorter mooring lines to reduce the mooring system footprint, and larger restoring forces to decrease the vessel offset (Loevstad et al. 1995). The synthetic fiber ropes have become one of the keys to the study of mooring systems due to the wide application of taut mooring systems on deep-sea drilling platforms (Johnsen and Ritsland 1999).

In 1997, Petrobras first used a polyester rope + anchor chain taut mooring system of the FPSO.

This mooring system can effectively reduce the vertical load and displacement under the harsh sea conditions compared with the anchor chain and the steel cable, saving a lot of economic costs. The rope comes in at a 30–45° angle on the seabed where it meets the anchor (suction piles or vertically loaded anchors), which is loaded vertically. When the platform drifts horizontally with wind or current, the lines stretch, and this sets up an opposing force.

Selection of Anchors

The major difference between a catenary mooring and a taut leg mooring is that when the catenary mooring arrives at the seabed horizontally, the taut leg mooring arrives at the seabed at an angle. This means that in a taut leg mooring, the anchor point has to be capable of resisting both horizontal and vertical forces (Fig. 2), while in a catenary mooring, the anchor point is only subjected to horizontal forces. In a catenary mooring, most of the restoring forces are generated by the weight of the mooring line. In a taut leg mooring, the restoring forces are generated by the elasticity of the mooring line (Loevstad et al. 1995).

Taut leg mooring system, which due to the taut profile of the lines, has no grounded line lying on the seabed in the nominal pretensioned condition. Therefore, the seabed anchor both are subjected to horizontal forces and vertical forces, and the mooring line anchor in a taut mooring line experiences an uplift angle (at the nominal burial point of the line) under pretension. Furthermore, the mooring line's uplift angle at the burial point can significantly exceed the 10° limit for high-holding capacity drag-embedment anchors. In this case, pile anchors, suction anchors, and vertical load anchors are more suitable for taut mooring systems.

The pile anchor (Fig. 3) is a hollow steel pipe that is installed into the seabed by means of a piling hammer or vibrator. The holding capacity of the pile is generated by the friction of the soil along the pile and lateral soil resistance. Generally, the pile has to be installed at great

Taut Mooring,
Fig. 2 Taut mooring line

Taut Mooring, Fig. 3 Pipe anchor. (From anchor manual 2005)

Taut Mooring, Fig. 4 Suction anchor. (From anchor manual 2005)

depth below seabed to obtain the required holding capacity.

The suction anchor (Fig. 4), like the pile anchor, is a hollow steel pipe, although the diameter of the pipe is much larger than that of the pile. The suction anchor is forced into the

seabed by means of a pump connected to the top of the pipe, creating a pressure difference. When pressure inside the pipe is lower than outside, the pipe is sucked into the seabed. After installation the pump is removed. The holding capacity of the suction anchor is generated by the friction

Taut Mooring, Fig. 5 Vertical load anchor. (From anchor manual 2005)

of the soil along the suction anchor and lateral soil resistance (Wang et al. 2012).

A new development is the vertical load anchor (VLA, Fig. 5). The vertical load anchor is installed like a conventional drag embedment anchor but penetrates much deeper. When the anchor mode is changed from the installation mode to the vertical (normal) loading mode, a VLA is installed just like a conventional drag embedment anchor. During installation (pull-in mode), the load arrives at an angle of approximately $45\text{--}50^\circ$ to the fluke. After triggering the anchor to the normal load position, the load always arrives perpendicular to the fluke. This change in load direction generates 2.5–3 times more holding capacity in relation to the installation load.

All three anchors have a common feature that can withstand horizontal and vertical loads. As VLA is deeply embedded and always loaded in a direction normal to the fluke, the load can be applied in any direction. Consequently, the anchor is ideal for taut leg mooring systems, where generally the angle between mooring line and seabed varies from 30° to 45° .

Advantages and Disadvantages

The structural analysis involving the taut mooring line is the same as the catenary, except that the taut mooring line can be regarded as a straight line, and it is easy to obtain its static characteristics. As for the dynamic analysis of mooring lines,

the lumped mass method and the slender rod theory are commonly used.

In general, the taut mooring system has four advantages compared to catenary mooring system:

1. The synthetic fiber has large recovery stiffness and provides greater restoring force, and the platform horizontal deviation decreases more.
2. Under the same water depth, shorter mooring cables are needed, which save costs, especially in deepwater and ultra-deepwater conditions.
3. The mooring line used in the mooring system is reduced in length while avoiding the application of large-mass steel chains, thereby reducing the mooring gravity, i.e., reducing the load on the platform and increasing the variable load of the platform.
4. With a small mooring radius, the mooring foundation occupies a small area of the seabed, reducing the risk of collision with other underwater facilities nearby. In the catenary mooring system, the catenary line has a larger vertical angle with the platform, so that the anchor chain has a large downward pulling force on the platform, which reduces the effective load of the platform. The application of the pontoon increases the mooring material and installation costs and increases the mooring drag force. The taut mooring system can effectively solve this problem.

The disadvantage of the taut mooring system is that the mooring needs to bear huge tension and axial stress under working conditions, so higher requirements are imposed on the characteristics of mooring modulus and life, and the floating structure is required to provide a large reserve buoyancy (Fan et al. 2010).

Definition

More than 90% of the world trade is transported by ships. Due to the growth of maritime transport, emissions from shipping are expected to increase 50–250% by 2050. Some countries have set up climate goal with 20% improvement of energy efficiency and a minimum of 10% renewable energy in transport sector by 2020. According to the inventory study carried out by Nelissen et al. (2016), the utilization of green energy as a ship's auxiliary propulsion is one of the most promising technologies to decarbonize maritime transport. In addition to reduce fuel cost and environmental impact, the requirements to comply with regulations on utilizing renewable energy will create large opportunities for the development of green energy technologies used in the shipping industry. Among all green energy technologies, the utilization of wind power as auxiliary propulsion seems to provide the most mature solutions in the market. The majority of the green propulsion technologies/concepts have been proposed only for bulkers, tankers, and general cargo vessels. However, from the shipping company's perspective, i.e., the demand side of wind propulsion technologies, only two commercial ships are installed a wind propulsion technology. While from the technology provider's perspective, only two providers' products are close to marketability, and all the other dozens of green propulsion technologies/concepts could be available but not before 2030. In the following, some facts regarding the green energy propulsion concepts will be given first. Then, technological barriers associated with the green propulsion technologies will be presented. Finally, the economic barriers connected with their marketability will be discussed. It should be noted that this section focuses on the barriers of wind propulsion technologies, which share similar problems with other types of green technologies concepts.

Technology Factors

Various concepts of green shipping technologies are under development, and the aim of these technologies is to optimize the utilization of

renewable green energy during a ship's sailing period. Taken the most promising wind propulsion technology, for example, for the conventional sail propulsive ships, it is important to evaluate/optimize the aerodynamic and energetic features of the designed wind propulsion technologies. That is the central issue because all technologies must provide enough power/propulsion forces to ships to make these concepts profitable to be installed onboard ships. Furthermore, when introduce these concepts to provide auxiliary propulsion in a merchant ship, some kinds of automation should be of high demand to be self-adjusted to various wind conditions without causing any extra work load of the crew. Moreover, equipment should be considered for conditions that the green shipping technologies are not allowed to be operated, e.g., in harsh weather conditions or harbor. The propulsion from these technologies should be minimized to keep the ship safe in those conditions. It should be noted that different concepts are associated with different degrees of complexity. For wind propulsion technologies, an inventory study by Nelissen et al. (2016) indicates their potential energy gains for tankers and bulk carriers listed in Table 1. In this study, five different well-recognized wind propulsion concepts are compared: Flettner rotor, sails/wingsails, towing kites, and wind turbines, for four potential ships. The sailing information of these ships are obtained from AIS-recorded ship passage profiles, and the wind technologies characteristics are based on the current state of development. However, the results from the inventory analysis to a large extent depend on the assumptions and parameters defining the wind propulsion devices. The analysis simply provides a preliminary results/energy saving that can be realized by such concepts. In the final marketing stage, a specific technology may be further optimized with respective to each individual ship and trade factors like investment cost, ease of installation/operation, and others.

It should be noted here that for those big ships, only 1% of the energy saving can mean hundreds of thousands of USD fuel saving every year. As shown in Table 1, except for the wind turbine concept (this idea is to install a commercial

Technical and Economical Barriers on Green Energy Utilization in Shipping, Table 1 Average energy savings using different wind propulsion technologies based on the AIS information of each ship type for their average operation profiles (Nelissen et al. 2016)

	Flettner rotor (%)	Wingsail (%)	Towing kite (%)	Wind turbine (%)
Large bulk carrier	17	18	5	2
Small bulk carrier	5	5	9	1
Large tanker	9	9	3	1
Small tanker	5	5	9	1

windmill onboard a ship to provide electricity and possible propulsions to ships.), all other concepts show big potential to be exploited in the shipping market. Furthermore, the relative energy savings from auxiliary propulsion concepts are higher for ships sailing at lower speed. This is because first the lower speed sailing ships may require the much lower power and, second, the energy gains from those green shipping propulsion concepts are also higher due to relatively higher auxiliary propulsive power. In addition, larger vessels can be installed green shipping propulsion devices of large power capability, leading to higher auxiliary power capture (energy saving).

Even though the above inventory study indicated large potential energy saving by installing such green shipping propulsion devices, it is still not recognized as mature technologies acceptable for current shipping companies to make practical investment. The barriers that hinder market installation are very complex. It can be categorized into technical and economic barriers, which will be further described in the following two subsections.

Technical Barriers

In principle, most of technical barriers are associated with the factor that those concepts are often provided with lack of reliable evaluation

procedure to convince customers regarding their actual gains (energy saving) against the practical investment. This kind of information requires reliable life cycle cost-benefit evaluation of those green shipping concepts. This evaluation needs multidiscipline knowledge and tools such as naval architecture, sea environments, mathematics and programming, etc. to develop the generic analysis method and optimization tool. In addition, to ensure ship safety with encountered extreme storm conditions, it is important to understand and simulate the physical phenomena of aerodynamic (wind forces from sails) and hydrodynamic (wave forces on ships) interactions. Good understanding of all these disciplines will also boost further development of the concept, as well as to educate our students as future naval architects. In summary, the key technical barriers can be related to reliable data on a ship and devices' mutual performance, operability, economic potentials and safety, as well as incentives from shipping markets/regulations to improve ships' energy efficiency and reduce CO₂ emissions from ships.

Design and Installation Challenges

The work efficiency of the green shipping concepts is of the greatest interest for their practical installation and practical applications. In general, to generate large propulsion force to provide auxiliary propulsion to merchant ships, the green shipping technology devices should be appropriately big enough. Consequently, the investment to design, construction, and installation is usually a big amount of cost. In addition, some of these technology devices should be designed specifically for individual ships to obtain larger energy gains than their actual investment for practical installations. For wind propulsion concepts, the aerodynamic performance of these devices was extensively studied via both wind tunnel tests and even the CFD (computational fluid dynamics) analysis, e.g., Flettner (1925), Blackford (1985), Argatov et al. (2009), Johnson and Andersson (2011), Cooke Association (2014), etc. However, the reliability of those established performance

models of these devices obviously requires further development. For example, some devices have a high weight and center of gravity, which may affect a ship's seakeeping behavior and also a high installation cost. In unfavorable winds, wind propulsion devices will create large drag forces, which may lead a ship to dangerous conditions of large ship heeling. Furthermore, since large wind devices have to be operated by cranes, for conditions that the height of devices is large enough to affect a ship's normal navigation, such as passing a bridge with marginal height clearance, the fold/launch equipment will significantly increase the installation cost (Bose 2008).

Furthermore, due to the severe working environments (high moisture and salty) of these green shipping devices, long-term maintenance cost during their operations should be seriously considered. For ship owners, the preferred payback time of their investment is 5–10 years. But usually the current payback time is often longer than that. For example, according to O'Rourke (2006), in order to install the most "simple" wind device such as a skysail, the cost of retrofitting a cargo ship with a row of masts, and strengthening the ship to dissipate stress due to the sail, was estimated to be approximately €10 m, around 15 years to recoup their costs through fuel savings. In addition, usually large amount of maintenance cost are associated with the initial installation investments of such expensive devices. The maintenance sometimes could double the payback time. It should be noted that the fuel saving cost is also strong related with future market oil price and future fuel cost scenarios for reduction of shipping emissions (Eide et al. (2011) and Faber et al. (2009)), which may shorten the payback time and make the wind-assist concepts more attractive to the shipping market.

For example, due to large forces generated by the wind devices, ships' structural components should be strengthened to enhance ship structural safety. For example, following the success of wingsail implementation on the tanker Shin Aitoku Maru, another vessel installed a similar wingsail onboard went wrong during high wind in a Japanese harbor. The big forces partly from the wingsail broke moorings of the vessel, which

was blown across the harbor. She seriously damaged other vessels in the harbor as well as the harbor itself. The accident discredited wingsail safety and indicated further technical development of such wingsail applications.

Operational Challenges

In addition to the design and construction of wind-assist devices, operation of the ship fitted with these devices and associated handling/control system requires robust performance prediction models to describe ship and wind devices' response in real ship operations. It is known that numerically modelling complex ship motions in real sea environments has always been one of the greatest challenges for the hydrodynamic analysis in the maritime industry. While the modelling of wind-assist ship performance requires even more sophisticated aerodynamic and hydrodynamic coupling analysis.

It is known a sailing ship sails with a constant heel and leeway angle to make use of wind propulsions to power the ship, while current merchant ships are mainly powered by marine engines connected with well-designed propellers. The installation of auxiliary wind propulsion devices will add at least two extra wind forces to ships depending on the number and arrangements of the devices. Wind forces, which should be big enough to ensure device-working efficiency (note that large wind-assist devices may block a ship's operation view on the bridge, which is quite essential in port operations), will significantly affect a ship's response behavior such as ship resistance, propeller efficiency, ship maneuverability, ship motions, etc. Furthermore, drag and lift forces generated from wind-assist devices have to interact with the thrust force provided by a ship's propellers. The ship's sailing course might be also affected by such interactions. To achieve highest work efficiency of these devices, an optimization procedure should be developed to guide the operation of the ship. It is often referred to routing optimization (optimum voyage plan) systems. In this case, routing optimization is a key factor to help captains to operate their ships to

maximize the utilization of wind propulsion through the iterative consideration of wind device performances and the ship's main power management to achieve the expected time of arrival with minimum fuel cost. In the following section, the characteristics of routing systems available in the current shipping market will be summarized in order to give a state-of-the-art description of such a service. It is expected to indicate further development requirements and directions to consider the wind-assist device in the future routing systems.

Moreover, the fuel savings by implementing these devices could be even maximized through the optimized planning of ship routing for each individual ship voyage. Currently, most of ocean-crossing vessels are instrumented with routing plan system, where routing optimization tool is used to assist ship operation in a more optimal way based on weather forecast information. The routing tool has the potential to save up to 5% of fuel cost and reduce 50% structural fatigue damage (Mao et al. 2012). The routing optimization system is also one of the key factors to maximize the use of wind propulsion in practical shipping. (Spaans 1985) investigated different optimization algorithms for the utilization of wind-assist devices to reduce energy cost of shipping. However, there is no routing tool, which can consider lift and drag wind forces for the routing optimization.

The Uncertainty of the Cost Efficiency

In general, there are large uncertainties included in the estimation of fuel savings by implementing these devices. Most often, these energy-saving devices need large amounts of investments for their implementations. One important uncertainty is due to lack of reliable methods/models to predict the performance (aerodynamic and hydrodynamic coupling analysis) of these devices in the real operation conditions, e.g., WASP (1985), WINDTECH (1985), etc. Another reason is that the estimation of fuel savings should rely on the encountered sea environments (trade routes, wind, wave, etc.) of a ship's future sailing service.

In addition to the nontransparent data and models for energy-efficient assessment, other barriers that hinder the implementation of the energy-saving measures in the shipping market are categorized by Jafarzadeh et al. (2012), which was carried out based on extensive market survey by Faber et al. (2009), Cagno et al. (2013), etc. As the case study mentioned in Nelissen et al. (2016), Fig. 1 presents uncertainties of energy saving by implementing four wind propulsion concepts for four different ships. In most cases, the scatter of potential energy gains is quite big. The technology providers should develop methods to evaluate energy saving provided by their technologies in a more accurate basis to convince potential customers in the shipping market.

In addition, services of implementing the measures within machinery system are often provided by large marine engine companies. The main barriers for such implementations are also connected with economic concerns from ship owners' perspective, or organizational barriers that the shipping company may have different priorities in comparison with the measures' implementations. Information barriers are of essential for the application of such measures, since the data and analysis provided by engine companies are often lack of transparency. The consequence is that larger percentages of energy savings are claims than it is actually observed in the market. The information barriers can be also found in retrofitting energy-saving

Technical and Economical Barriers on Green Energy Utilization in Shipping, Fig. 1 Average absolute power savings (solid symbols show savings averaged over sample

routes, empty symbols averaged over sample fleet voyage profiles from AIS tracks)

devices, such as installing a duct to harmonize and stabilize the flow distribution entering into the propeller to increase propulsion efficiency, reconfiguration of propellers, etc. On the other side, the lack of information can be also induced by the lack of technical solutions to prove the efficiency of the energy-saving devices.

Currently, the technical maturity of these measures should be further developed to ensure the confidence to estimate their investment and payback time, for example, the utilization of wind power for ship auxiliary propulsions. Even though large potentials can be expected from such measures, their arrangement onboard ships, installations, maintenances and its impacts to a ship's overall safety and maneuverability, as well as the optimum utilization of the wind forces provided by them require a complex system with different levels of models and technologies to support the whole concept. In addition to retrofitting or updating sub-systems in the existing ships, optimal ship operation managements, such as slow steaming, optimization voyage plan, etc., are rather cheaper but straightforward, efficient, and most implemented measured in the shipping industry.

Because of fast advancement of information and communication technology, the increased reliability of weather forecast provided by meteorological institutes, large amounts of free access to marine weather measurements, robust communication between onshore operation office and ship bridges, and more energy saving from the optimal ship operation will be realized through the development and implementation of optimization voyage plan system by integrating different levels of measures, such as wind power devices.

Market Potential and Economic Barriers

According to the inventory study carried out by Nelissen et al. (2016), only for the utilization of wind power concepts as auxiliary propulsion, the maximum market potential installation onboard commercial ships is estimated to be around 3700–10,700 devices/systems until 2030. It contains the installation for both retrofits and installations on newbuilds, and the precise number of

installations depends on the future bunker fuel price, and the cost reduction of these technologies can be achieved because of economies of scales through mass production. The use of these wind propulsion systems would help to reduce CO₂ emissions to around 3.5–7.5 Mt in 2030.

Even though there is a large market potential for the green shipping concepts, the diffusion process may not be perfectly mature in 2030 yet, and it is expected to occur when more newbuilds have entered the market with observed profits from their installations. Before the mass penetration into the market, in addition to the technical barriers, economic hindrances are also referred to the interorganizational barriers for the implementation of energy-efficient measures. For example, even within a same company, top managements may have different motivations from technical advisors to update their conventional designs to the more energy-efficient ship concepts, which are often associated with risk of the actual energy gains through the new implementations. In some cases, the organizational barriers are also combined or due to the technical maturity of certain measures and methodologies. For example, it is well recognized that a ship's optimization design should be carried out for her actual operational conditions and future service weather environments, while the construction contracts between shipyards and ship owners are normally referred to the calm water condition with specific service speed. All the sub-systems should be arranged and optimized based on requirements for the ship operated in calm waters, while ships are rarely sailing in such conditions. The reason behind is that the mature information and technology for such condition is available to judge the success of the ship construction project. Furthermore, the incentive for current shipping companies is mainly associated with the compliance to environmental regulations to improve the energy efficiency in ships. The factors of making actual profits through the installation of energy efficiency technologies are not solid/mature enough to convince the shipping market.

To breach the marketing problem, a standardized method to assess green energy propulsion

systems should be developed and validated with test cases. Only if assessable information produced through the standardized approach by an independent party, ship owners and investors could be convinced for practical investment and public funds for practical installation. On the other side, it will motivate the further development of the technology and provide valuable information regarding actual gains through the development. When developing a standardized method to assess practical gains by the green shipping concepts, the consistency of the regulation incentives, such as the Energy Efficiency Design Index (EEDI), technical guidance for the conducting performance tests of those technologies should be carefully considered. It should be noted to the market that the determination of the actual fuel savings is preferable.

Definition

A *tension leg platform (TLP)* or *extended tension leg platform (ETLP)* is a vertically moored floating structure normally used for the offshore production of oil or gas and is particularly suited for water depths greater than 300 m (about 1000 ft.) and less than 1500 m (about 4900 ft.). Use of tension leg platforms has also been proposed for wind turbines (https://en.wikipedia.org/wiki/Tension-leg_platform).

Introduction

With the increase of water depth, a tension leg platform (TLP) was developed based on the semisubmersible platform in order to optimize the heave motion of the platform. The tension leg platform consists of the upper block, the floating body, the tension leg, the top tension wellhead riser, the catenary riser (external/internal input), and the pile foundation. Several tendons composing the tension connected to the foundation of the subsea pile serve to tighten and fix the platform and control the movement of the floating body within a certain range. TLPs are divided into two types, traditional and new ones, and subdivided into four types, conventional TLP, Seastar TLP, MOSES (MOSES TLP), and extended TLP (ETLP).

One of the most important characteristics of TLP platform is that its buoyance is larger than its weight, which leads to the large tension in the tendons. Therefore, TLP platform can be regarded as an inverse pendulum, which brings TLP platform not only outstanding motion characteristics but also strict requirement on onboard weight control.

Distribution Worldwide

According to the latest statistics of *Offshore Magazine*, there are 26 TLP platforms in the world, including 11 conventional TLPs and 15 new generation TLPs; 16 of them are in the Gulf of Mexico, 1 each in the UK, Brazil, and Indonesia, and 2 each in Norway and Angola and Equatorial Guinea; of the 25 platforms, 7 are wet tree oil production, 1 has dry and wet tree oil production, and 17 are completely dry trees.

Since 1984, there have been many TLP platforms that have been put into production and operation in the world. They have excellent working records, which has strengthened the confidence for industry's structure of the emerging offshore platform of TLP. During its development, researchers and engineers from all over the world have accumulated rich experience in design and application and technical data, laying a solid

foundation for the development of the TLP platform.

TLP platform has a wide range of working water depths and oil production modes. Different countries have formed different oil production modes according to the characteristics of their own sea areas. At this moment, the “American model” and the “Brazil model” are the most typical ones. The “American model” is a semi-sea semi-continental type, which is like the engineering model of “floating drilling platform (TLP/SPAR) – underwater wellhead/underwater production system – submarine pipe network.” The Brazilian model belongs to the all-sea model, that is, the oil and gas field development engineering model of “semisubmersible platform – underwater wellhead/underwater production system – floating production storage and offloading unit (FPSO).” In addition, the South China Sea oil production model can draw on the successful experience of the USA and Brazil to form an oil field development model of “floating drilling platform, FPSO, and underwater wellhead/underwater production system” (Figs. 1 and 2).

History of TLP Development

In 1954 American R. O. Marsh proposed a TLP scheme with a cable group fixed by tilting

mooring in the first place, which immediately attracted great attention from offshore engineers. In 1962, the British Petroleum Development Corporation built a 124 t triangular TLP test platform called “Triton” at a site with water depth of 30 m in the Scotland coastline. It is proved that this platform has excellent motion performance in waves. In 1974, the US Deepwater Petroleum Technology Company placed a 650 t TLP test platform named “Deep Oil X-1” at a depth of 60 m in the waters around California, conducting 5 years of experimental research and theoretical analysis on its movement. At the same time, the marine engineering research institutions in Japan, Italy, Norway, the Netherlands, and other countries have invested a lot of manpower and resources to carry out a large number of investigations, on TLP’s overall performance, main scale optimization, tension leg tension characteristics, and specific links in the process of construction and installation.

Based on nearly 30 years of experimental and theoretical investigations, in August 1984, the world’s first practical TLP was completed and put into operation by Conoco in the water depth of 157 m in the Hutton oil field in the North Sea of the UK. Subsequently, in November 1989, Continental Petroleum Corporation built a tension leg wellhead platform at a depth of 528 m in the Jolliet oil field in the Gulf of Mexico. In 1992, Saga Oil Company of Norway built a large

Tension-Leg platform,

Fig. 1 US oil and gas development model

Tension-Leg platform,

Fig. 2 Brazil oil and gas development model

TLP in the Snorre field in the North Sea of Norway with a water depth of 340 m. In June 1995, Conoco installed the world's first concrete TLP at a depth of 330 m in the Heidrun oil field in the North Sea. In 1996, Shell and BP Exploration installed the Mars tension leg platform in the Canyon 807 block in Mississippi, USA, to rewrite the water depth record to 880 m. The first SeaStars TLP was built in 1998, the first MOSES TLP was built in 2001, and the first ETLT was installed in 2003.

The development status of TLP platform in recent years is as follows (Table 1).

Structural Components of TLP

Description

The main body of the traditional TLP platform is generally rectangular or triangular. The upper body of the platform is above the water surface. The lower body is connected to the upper body by four or three columns which are the cylindrical structure. The main function of these columns is to provide the necessary structural rigidity to the platform body. The buoyancy of the platform is provided by a sinking pontoon located below the surface of the water, and the head and tail of the pontoon are connected to the columns to form a ring structure.

The tension leg is composed of 1–4 tension tendons. In terms of these tendons, the upper end is fixed on the platform body, and the lower end is connected with the submarine base template or directly connected to the top of the pile foundation. Sometimes in order to increase the lateral stiffness of the platform system, a diagonal mooring system is also installed as an aid to the vertical tension leg system. The foundation on the seabed is fixed in place, mainly in the form of pile foundation or suction foundation. The central well is located on the upper body of the platform and can support the dry tree system. The production riser is connected to the production equipment through the middle well and is connected to the subsea oil well (Figs. 3 and 4).

An TLP platform normally has five parts of structural composition:

1. Upper platform: The upper body of the platform refers to the part above the lower deck of the TLP. It is equipped with production, living equipment, and auxiliary facilities. The shape of the platform can be triangular, quadrangular, and pentagon, but majority of TLP platforms use quadrilateral shape. The main function of upper platform is to support the production module, accommodation module, helicopter deck, etc.
2. Column: The columns are mostly larger diameter cylinder. The number of columns depends

on the shape of the upper body. In order to ensure the strength, some columns are also provided with cross braces and diagonal braces. The main function of the column is to provide buoyancy to the structure, to ensure that the platform has sufficient stability to support the upper deck structure.

3. Pontoon: The pontoon can be divided into three types according to the structure type: integral type, combined type, and sinking type. The main function of the pontoon is to provide buoyancy for the platform, together with the column to ensure the stability and floating state of the platform.
4. Tension leg: The tension leg connects the platform body and the anchoring system of the seabed, which ensures the relative fixation of the platform structure position, controls the motion response of the platform, and ensures the platform has good motion performance. The tension leg system consists of a plurality of sets of tensioned steel cables. The number of sets is related to the shape of the upper body of the platform. Each set of cables is composed

of a plurality of tendons, and the tension generated therein is balanced with the remaining buoyancy of the platform. The tension leg system not only controls the relative position of the platform and the wellhead but also plays a decisive role in structural safety.

5. Anchoring foundation: The anchoring foundation is an important part of the TLP platform, which plays a fixed platform and precise positioning. There are two types of anchoring foundation which are gravity foundation and pile foundation. In addition, there is some other type of anchoring foundation, for instance, the TLR of the Snorre oil field in the North Sea has adopted the concrete suction anchor fixing system.

Tendon System

Introduction to the Tendon System

The tension leg platform (TLP) is a typical compliant platform that is connected to the sea floor by several tendons. The tendon system is an important part of the tension leg platform (TLP) in order

to guarantee the platform is securely anchored to the seabed foundation. The tendon system is always in tension and its axial rigidity is large, which limits the heave, pitch, and roll motions of the platform to a small extent. Its horizontal compliance limits the platform’s sway and roll to an acceptable range of operation and ensures that the platform body in harsh waves is still capable of uninterrupted production operations under environmental loads such as currents and winds. The tendon system consists of multiple tendons and load measurement systems, inspection, or monitoring devices. A single tendon consists of three main parts: a platform interface, a subsea interface, and a body that connects the two interfaces. Each part can contain multiple components, and the form of each component varies depending on

the specific design. Figure 5 shows the tendon structure.

Design of the Tendon System

The tendon system design should ensure that the tendon system meets operational, installation, material, inspection, stress, and fatigue requirements. The tendons designed can be permanent or removable. Additionally, regardless of whether the tendons are permanent or not, the tendon system should be designed to have the potential to remove a tendon.

The selection process of tendons in the tendon system is as follows:

- 1. Calculate the displacement of the platform at this draft according to the main scale of the

Tension-Leg platform,
Fig. 5 Tendon structure.
(Picture from <http://www.offshore-mag.com/>)

tension leg platform and the corresponding draught information.

2. According to the calculated displacement of the platform, determine the number of tendons and the tension coefficient (tension coefficient = total pretension/platform displacement, for example, 30%) and then calculate the pretension required for each tendon.
3. The selection of pipes with a variety of outer diameters can be made according to classification society rules, for example, API SPEC 5L "Pipeline Steel Pipe Specification" (43rd Edition), to calculate the weight of the pipe under different wall thicknesses and select the pipe that meets the demand of $0.8 \leq \text{floating weight ratio} \leq 1.0$.
4. The selection of an appropriate outer diameter and wall thicknesses of the tendon must also be made according to classification society rules, for example, API RP 2T "Recommended Practices for Planning, Design and Construction of Tension Leg Platforms" (3rd Edition) and API RP 2RD "Recommended Practice for Design of Floating Production Systems and TLP Risers" (1st Edition).

Tendon System Installation

In the installation process of the tension leg platform, the tendons are firstly connected with the seabed. When the connection between all the tendons and the seabed is completed, the main body of the tension leg platform is transported to the working sea area to connect with the tendons. After the tension leg platform tendons are connected with the seabed pile foundation, the tendon support buoy (TSB) is required to provide sufficient buoyancy for the tendons to ensure that the tendons do not tip over before the platform reaches the working waters. After the ribs are connected to the main body of the platform, the TSB is released. If the buoyancy provided by the pontoon is insufficient or faulty, the ribs will collide with each other to invalidate the ribs or even overturn the entire tendon, so that the installation of the tension leg platform cannot continue (Fig. 6).

Influence of the Tendon System on the Hydrodynamic Property of the Platform

The nonlinear recovery stiffness provided by tendon system plays a very important role in dynamic responses of TLP platform. The six-degree-of-freedom motion of TLP can be easily divided into two categories, one is mainly controlled by the mooring system stiffness, including the roll, heave, and pitch motions in the vertical plane; the other is mainly determined by the geometric form of the structure and the horizontal component of the mooring tension, including the surge, sway, and yaw motions in the horizontal plane. Due to the large stiffness generated by buoyancy and gravity difference, the natural period of motion on the vertical plane of TLP is relatively small, and the natural period of motion on the horizontal plane is generally large. The natural period of the heave motion is generally within 2–4 s. The horizontal system stiffness is only the small angle positive component of the pretension. The natural period of the longitudinal and vertical motion is generally within 100–200 s. The unique structural form of TLP largely avoids a large displacement caused by the wave excitation load resonance.

The tendon system makes the natural periods of TLP's motion far away from the resonance periods zone of the wave spectrum. Under the effective constraint of tension tendons, the tension leg platform can avoid the resonance frequency of wave energy concentration, which makes the platform significantly improved in longitudinal, roll, and heave performance. It greatly improves the application range, comfort, and safety of the platform. The increase of the pretension can effectively reduce the motion response of the platform and the angular displacement response of the tendons. While maintaining the draught, the increase in the number of tendons can simultaneously increase the horizontal flexibility and vertical rigidity of the platform movement.

Mini TLP

Mini TLP appeared in the early 1990s. It inherits the advantages of traditional TLP's excellent hydrodynamic performance and good economic

Tension-Leg platform,

Fig. 6 Installation process of the tendon. (Picture from <http://www.cotecinc.com/>)

benefits and optimizes the structural form, which makes it low in cost, small in size, flexible, and environmentally friendly. The utility model has the advantages of small hydrodynamic load and stable operation in a deepwater environment. Therefore, it is more suitable for deep-sea operation, harsh marine environment, and small and medium oil field development in deep-sea area, due to its reduction of construction cost and oil field development. The Mini TLPs currently in production practice are mainly divided into two categories, namely, SeaStar TLP and MOSES TLP.

SeaStar TLP

The main body of the platform breaks the traditional type of T-concave 3-column or 4-column

structure, using a very unique single-column design. This cylindrical structure is called the central column. The central column passes through the horizontal plane. The upper end of the column supports the platform deck. At the lower end of the column, the three horizontal cross-section buoys are fixed by internal horizontal and diagonal pull-ups. Each float extends outward forming the cantilever beam structure. The angle between each other on the horizontal plane is 120° , forming a radial shape, and the end cross-section of the pontoon gradually reduces. The three buoys provide buoyancy to the platform body and are connected to the tension leg system at the outer end. The central column includes a casing wall, a moon pool, or a passage. The interior space of the platform is divided into a series of

Tension-Leg platform, Fig. 7 SeaStar TLP

watertight spaces. The six tension legs extend vertically from the joint at the end of the pontoon to the submarine pile foundation. The buoyancy of the pontoon pulls the tension leg, and the buoyancy of the center column supports the deck load to ensure the stability of the platform against subversion. Figure 7 shows the basic composition of the SeaStar Mini TLP.

The SeaStar TLP platform inherits the superior motion characteristics of the traditional TLP platform, with small fluctuations in heave, roll, and pitch. The single cylinder design eliminates crushing and pickup loads in traditional TLP platforms, and the deck design is simplified and modular. The small cylindrical structure reduces the influence of the water line surface dynamics, so that the motion sensitivity problem of the upper equipment is reduced. The small cylindrical structure also saves construction and installation costs, shortens the construction period, and is very suitable for developing large marginal oil fields. However, the SeaStar TLP platform also has some shortcomings. The single cylinder design makes its towage ability or free-floating stability very poor. It is also sensitive to the quality of the superstructure, which makes the superstructure

very limited. When the main body and the superstructure are installed, suspension assistance is required. The entire system is rigid and has extremely high requirements for tension legs.

MOSES TLP

Deepwater tension leg platforms (TLP) are normally unsuitable for small- or medium-sized deepwater fields because of their inherently high Capex costs. Thus, a new, small low-cost TLP design was developed that can be delivered in relatively short timescales and be provided to operators on a lease basis. The minimum offshore surface equipment structure (MOSES) was designed for small fields located in moderate/deepwater depths (Wybro et al. 1995).

The main body of the MOSES TLP still follows the design of the square column structure of the traditional TLP. The platform buoyancy is mainly provided by a floating cabin located in the platform base. The platform base is below the water surface and has a special shape. The center of the base is a square body, and each edge extends diagonally to form a cantilever beam structure. The longitudinal section of the beam is triangular, and the tension leg system is attached to the edge of the four cantilever beams. The column is integrated with the base and is located on the four corners of the top surface of the base. At the same time, the four columns arranged centrally have a certain shadowing effect, and to some extent, the environmental load on the platform is reduced. Moreover, the riser system is connected along the outside of the platform to an open space that is installed at one end of the platform away from the center. This design reduces the possibility of collisions in the riser system. Figure 8 shows a MOSES TLP platform.

MOSES TLP continues to use the traditional four-corner platform structure design to provide greater support for the upper body of the platform and improve the stress on the deck, thus reducing the construction cost of the upper body. The column is thinner than the traditional TLP platform, and the force area at the waterline surface is small, which reduces the wave load on the platform. The modular design of the main body saves a lot of trouble in the construction process and can be manufactured using the standard production line

Tension-Leg platform, Fig. 8 MOSES TLP

of the shipyard. At the same time, the special design of the platform body also greatly reduces the motion response of the platform in the “fatigue zone,” which can reduce the pretension in the tension leg system of MOSES TLP, greatly simplifying the design of the tension leg system. The tension leg system of the platform is manufactured using standardized components, reducing manufacturing costs. And for the first time, a passive spring riser tensioning system is used, which replaces the traditional hydraulic and pneumatic tensioning system, and its safety and stability are greatly improved. In addition, the cost of the whole system is lower, the structure is simpler, and the influence from the environmental load is reduced. In addition, MOSES TLP is simple in structure and flexible in installation. It can be applied to the installation of a variety of deep-sea equipment.

Definition

Thermal insulation refers to laying thermal insulation layer on the surface of heat supply pipeline and its accessories to reduce the invalid heat loss of heat medium in the process of transportation and maintain certain parameters of heat medium to meet the needs of users.

Background

As oil and gas exploration enters the deep sea mode, the low-temperature and high-pressure environment in the deep sea is more conducive to the formation of hydrates and wax crystals,

thereby blocking the submarine pipelines. Once the hydrates or wax crystals are formed in the pipelines, the transport capacity of the pipelines is affected. It will cause major engineering accidents. Insulation measures for submarine pipelines to prevent the formation of hydrates and wax crystals have also been continuously studied since oil and gas exploration.

The type of insulation can be divided into passive insulation and active heating.

Passive Insulation

Passive insulation includes dry insulation and wet insulation. Passive insulation is achieved by using the properties of the insulation material and the pipe structure to achieve its insulation effect. For submarine pipelines in deep water, the way to maintain insulation by virtue of the properties of the materials is extremely demanding, including materials that need to meet high strength, high hardness, high hydrostatic pressure, and creep resistance, and is quite expensive. In the process of passive insulation, chemical reagent injection methods, usually methanol and ethylene glycol, are often used to inhibit hydrate formation and wax deposition, but the injection of chemical reagents requires a rigorous calculation, because the injection of chemical reagents tends to reduce the amount of flow rate. For passive insulation, the most deadly drawback is that in the process of shutting down and opening the well, it will promote the formation of hydrate and wax crystals due to passive insulation.

At present, most of them adopt measures such as heating on the offshore platform and combining double-layer insulation pipes and chemical injection reagents and pigging to ensure the safety of conventional and short-distance oil pipelines. This requires not only a large electric heating device but also for heavy oil or long-distance oil and gas transportation. The abovementioned deficiencies can be well solved by using submarine pipeline active heating technology. Especially in the deep water long-distance return system or in the cold Arctic region, the advantages of active heating technology are more prominent.

Active Heating

Submarine pipeline active heating technology can be divided into hot fluid and electricity according to the different heat sources used, as shown in Fig. 1. Active heating technology has been applied to subsea pipelines in multiple oil and gas fields.

Hot Fluid Heating

Thermal fluid heating is a traditional method of heat tracing. The method is to ensure the normal transport temperature of the medium in the oil and gas pipeline by the heat exchange between the hot

fluid and the medium in the oil and gas pipeline and the external thermal insulation layer.

Depending on the type of pipeline structure, the hot fluid can flow in the tube loop cavity or the bundle tube heat pipe, which is called direct heat tracing and indirect heat tracing, respectively, as shown in Fig. 2. Commonly used hot fluids are sea water, production water, aqueous glycol solution, steam, and the like. The heat fluid heat source may be a heating device such as a boiler or a waste heat recovery system.

The hot fluid is directly heated, and the insulation effect is poor due to the wet insulation layer. For the indirect heat tracing of the hot fluid, the

Thermal Insulation, Fig. 1 Submarine pipeline thermal insulation technology

Thermal Insulation, Fig. 2 Outline of direct and indirect hot fluid circulations systems (McDermott and Sathananthan 2014)

thermal insulation effect is better because the dry heat preservation is adopted. However, current cluster pipes require specific construction sites, and the installation method and application depth are limited. Thermal fluid heating is a good choice when there is sufficient residual heat available on the platform.

At present, the Britannia oil and gas field in the North Sea, the King oil and gas field in the Gulf of Mexico, and the Puteri oil and gas field in the Malaysian waters are all directly heated by hot fluid; the Gullfaks South, Asgard, Skene, and Bacchus oil and gas fields in the North Sea are all using thermal fluids.

Direct Electric Heating

Direct electric heating is to directly pass current on the pipe wall, and the pipe is electrically conductive as a conductor, which generates heat due to the alternating current resistance of the pipe material, as shown in Fig. 3. The heat generated

by direct electric heating is related to the current and the AC resistance.

According to the different types of pipeline structure, direct electric heating can be divided into wet direct electric heating and direct tube electric heating. Wet direct electric heating is for single-layer pipes, and the cables are connected to the two ends of the pipe. The direct electric heating of the tube in the tube is for the double-layer tube structure, and the cables are respectively connected with the inner and outer tubes and can be divided into two types: end feeding and intermediate feeding according to different wiring positions.

The direct electric heating adopts the wet heat preservation, the heat preservation effect is poor, and the dry heat preservation has better heat preservation effect. Since direct electric heating is directly connected to alternating current on the pipe wall, there is a risk of AC corrosion, special design of anticorrosion is required, and regular

Thermal Insulation, Fig. 3 Schematic diagram of direct electric heating pipeline (<https://www.techreleased.com/wartsila-to-supply-direct-electric-heating-system-for-african-offshore-oilfield/>)

inspection and maintenance are carried out. At present, the direct electric heating type has low electrical efficiency and has not yet been validated for long-term use.

At present, Alve, Norne, Asgard, Huldra, Kristin, Urd, Ormen Lange, Tyrihans, Morvin, Skarv, and Skuld oil and gas fields in the North Sea and Olowi oil and gas fields in West Africa use wet direct electric heating. The Serrano and Oregano oil and gas fields in the Gulf of Mexico use the direct electric heating (end feed) type of the tube, and the Habanero and Na Kika oil and gas fields use the direct electric heating (intermediate feed) type of the tube.

Electric Heating

The working principle of electric heat tracing is to dissipate a certain amount of heat through the heat tracing medium and supplement the loss of the heat tracing pipe through direct or indirect heat exchange to achieve the work requirements of heating, heat preservation, or anti-freezing. The electric heat tracing is to heat the heating cable/heat tracing tube by the electric and magnetic effects of the cable/heat tracing tube, thereby transferring heat to the heat tracing pipe, supplementing the heat lost by the tracing fluid in the process flow, so as to maintain the most

reasonable process temperature of the flowing medium.

According to the different heat generation mechanism of electric heat tracing, it can be divided into electric heating cable heating, skin effect electric heat tracing, and electromagnetic induction electric heating. At present, the first two types of heating type already have subsea pipeline engineering applications, and the electromagnetic induction electric heating has no submarine pipeline engineering application and is still in the development stage.

Electric Heating Cable

Electric heating cable heating usually wraps the heating cable around the inner tube of the double tube, as shown in Fig. 4. Set a certain number of heat tracing cables based on the required heat, and set up a backup heating cable.

Electric heating cable heating generally adopts dry heat preservation, which has better heat preservation effect and higher thermal efficiency. The electric heating cable is relatively uniform in longitudinal and circumferential heating of the pipeline and has good operability. It can accurately control and adjust the heating energy and can monitor the heating temperature through the optical fiber. However, when the electric heating cable

Thermal Insulation, Fig. 4 Schematic diagram of electric heating cable (Candelier et al. 2015)

is laid by the coiling method, the diameter of the pipeline is limited by the capacity of the pipe laying vessel.

In addition, by combining the heat tracing cable with the flexible bundle pipe, an electric heat tracing flexible bundle pipe that can be applied to the riser pipe segment is formed, as shown in FIG. It can be used for active heat tracing of dynamic risers. However, the insulation effect is poor, similar to wet insulation (Fig. 5).

At present, the Islay oil and gas field in the North Sea has adopted electric heating cable heating; the Dalia oil and gas field in the West African waters and the Para Terra oil and gas field in the Brazilian waters have adopted flexible cluster tube electric heating cable.

Skin Effect Electric Heating

Pipe skin effect electric heat tracing technology is a new metal pipe heating method, referred to as SECT (skin electric current tracing) method. The skin effect electric heat tracing system is mainly composed of a process pipe, a heat tracing pipe

and a heat-resistant skin cable, an insulation layer, and a protective casing. The heat tracing tube is a ferromagnetic steel tube, and the heat-resistant skin cable is placed in the heat tracing tube, and the outer layer is an insulating layer and a protective outer casing. The structure is shown in Fig. 6.

According to the tube diameter and the heating temperature, the skin effect heating is divided into single-tube, double-tube, and triple-tube heating. The heat-resistant skinning cable is placed in the heat tracing tube, and the core wire of the cable is connected to the heat tracing tube at the end of the heat tracing tube. At the power supply end, the heat pipe and the skin cable are respectively connected to the AC power source. When the AC current flows through the heat-resistant skin cable and the heat-treating tube, due to the ferromagnetic characteristics and the proximity effect of the heat-treating tube, the skin effect phenomenon forces the current only in the inner wall of the heat tracing tube flows to generate thermal energy. The external surface of the heat tracing

Thermal Insulation,

Fig. 5 Schematic diagram of electric heat tracing flexible bundle pipe (Baker 2014)

Thermal Insulation,**Fig. 6** Skin effect electric heat tracing structure type (Ansart et al. 2014)

tube has no current, so the heat tracing tube can be safely grounded.

In 2008, the Weinan oil and gas field applied the skin effect electric heat tracing to the submarine pipeline. After the skin effect electric heating system was put into use, the pipe outlet temperature increased by about 5 °C (Denniel et al. 2004).

Electromagnetic Induction Heating

The basic structure of the electromagnetic induction electric heat tracing system is similar to the skin effect electric heating tracing, and the difference lies in the way of the remote connection. For electromagnetic induction heating, the three heat cables at the far end are connected to each other and grounded to form a neutral point. An alternating magnetic field is formed when the alternating current flows in the cable located at the center of the heat tracing tube, causing an induced circulating eddy current in the heat tracing wall. This circulating eddy is eventually dissipated as heat due to the alternating current resistance and hysteresis effect of the heat tracing tube. This heat is

transferred to the main line through the heat tracing tube to heat the fluid.

At present, no case of electromagnetic induction electric heating is applied to submarine pipelines.

A general comparison table of active heating technologies is presented here below (Fig. 7).

After comprehensive comparison and analysis, it is suggested that the following items should be considered in the selection and design of heat tracing modes for submarine pipelines:

1. The heat preservation effect of the insulation layer is directly related to the heat tracing efficiency. In general, the effect of wet insulation is obviously lower than that of dry insulation. Generally, when designing the heat tracing system, the influence of the insulation system on the heat conduction of the whole submarine pipeline should be considered comprehensively.
2. The heat tracing efficiency of hot fluid tracing is low, and the corrosion problem caused by hot fluid to heat tracing pipeline should be considered. When there is enough waste heat

		Hot fluid heating	Wet direct electric heating	Direct tube electric heating	Electric heating cable	Skin effect electric heating
DESIGN	Pipe type	Pipe in Pipe	Wet Insulated Pipe	Pipe in Pipe	Pipe in Pipe	Pipe in Pipe
	Weight	Heavy pipe	Light pipe	Heavy pipe	Heavy pipe	Heavy pipe
	U-Value (W/m ² K)	Wet:3-6 Dry:0.6-6	Wet:3-6	Dry:0.6-2	Dry:0.6-2	Dry:0.6-6
HEATING EFFICIENCY	Heating Efficiency	40-60%	50-70%	95-100%	90-100%	90-100%
	Electrical Efficiency	N.A.	30-60%	50-70%	90%	Close to 100%
	Max single heated length	Limited by pressure drop in water circulation system	Longest length installed to date: 28km	Longest length installed to date: 17km	20-50km due to cables rating limitations	Single power supply can heat tracing for 20 km in one direction
CONSTRUCTION & INSTALLATION	Installation Method	S&J Lay only	S&J Lay Reel lay	S&J Lay Reel lay	Reel lay	S&J Lay Reel lay
	Max Water Deep	High for small diameter pipes	0-400m	High for small diameter pipes	Tracing cables qualified for 1500m WD max	High for small diameter pipes
	Max Diameter	About 12" inner pipe max	6" to 30" Corresponding to S-Lay Capabilities	About 12" inner pipe max	About 12" inner pipe max	About 12" inner pipe max
OPERABILITY	Continuous Heating	Yes	Yes in Shallow Water. Not qualified in Deep Water	Not qualified	Qualified	Yes
	Precise power adjustment	No	No	No	Yes	Yes
	Temperature Monitoring	Only at the inlet and outlet	Only DTS monitoring in the power cable	Fiber Optic Measures	Fiber Optic Measures	Fiber Optic Measures
COST	Engineering and process	Cheap Wet Insulation. Expensive Dual pipe structure	High rating piggy back cable + 2 Dynamic umbilical	Expensive Dual Pipe structure + 2 Dynamic Umbilical	Expensive dual pipe structure + High performances Insulation	Expensive dual pipe structure

Thermal Insulation, Fig. 7 Active heating technologies – comparison table (Esaklul et al. 2003)

available on the platform, hot fluid tracing has great advantages (Nebell et al. 2013).

3. The electric efficiency of direct electric heating is low, so it is necessary to design special

anticorrosion and carry out regular inspection and maintenance. At present, most of the direct electric heating pipelines are short-term use, rarely long-term use.

4. It is suitable for long-term use because of its small temperature gradient and long thermal stability time. The heat (electric power) required by electric heat tracing is obviously lower than that of direct electric heating.

Prospect

Active heating technology and passive insulation technology can make subsea pipeline operation more flexible and reduce the sensitivity of underwater production systems to transient operating conditions, especially under deep water and high hydrostatic pressure conditions.

Electrically trace heated PiP technology is the next evolution of active heating systems that combine high-performance thermal insulation with a low power design making it a very attractive option in comparison to conventional DEH systems. In the future it is expected that the major industry drivers will be toward the development of smart oil fields of the future which will require continual development and innovation of active heating systems technology.

Definition

A **thruster-assisted mooring (TAM)** system has different control functions for station keeping and motion damping for a moored offshore vessel with assist from thrusters. It consists of a conventional passive mooring system and a so-called dynamic positioning (DP) system. Actually, it is not the simple superposition of the two systems. The thrusters are used to provide damping and some restoring to the vessel motion and withstand environment loads. In addition, if line breakage occurs, thrusters need to produce more force to compensate. The mooring system absorbs the main loads to keep the vessel in position.

Scientific Fundamentals

Development of Thruster-Assisted Mooring

When offshore operations are discussed, it is commonly thought of as the various tasks related to oil and gas production and exploration at sea. Oil production is probably one of the most technologically advanced and challenging operations on the ocean. According to the type of operation, a structure might need to stay at the working spot on the ocean for everything from shorter day missions and a few months of exploration to a several years-long production period.

A common solution for long-lasting operations on relatively small water depths is to build a solid structure which can stand firmly on the seafloor. It

can keep the platform steady without any energy consumption, but it is less flexible and requires more time for installation to get in position.

So it is necessary to use a floating structure in deeper water. There is also an advantage in general that it requires less amount of effort needed for installation. For some shorter-lasting operations, the easy-come-easy-go floaters are more cost-effective. These can be kept in working position by the use of anchors and mooring lines. The drawback of this solution is the vulnerability when the waves and other periodical loads act on the floating structure, leading to potentially large oscillations due to the spring effect from the mooring lines and the relatively low damping of the system.

By introducing a control system and thrusters, the floating structure can be kept in target position automatically, while active damping can be used to prevent large horizontal offsets. It led to the introduction of dynamic positioning (DP), making it possible to stay in place without any time-consuming external installations and with no need of seafloor installations. Figure 1 shows the basic conception of TAM system on a semisubmersible platform.

In recent years, thruster-assisted mooring (TAM) systems have become more commercially available, especially in the oil industry. For semisubmersibles, it is suitable to use spread moored systems. For FPSOs, both turret mooring systems and spread mooring systems are used according to the working conditions.

Thruster-Assisted Mooring, Fig. 1 Basic conception of TAM system

Thruster-Assisted Mooring, Fig. 2 Spread mooring systems. (<https://www.bluewater.com>, <http://www.dredgingengineering.com>)

Basic Technology and Theory of Thruster-Assisted Mooring

Mooring system is one of the key systems in TAM system. A mooring system refers to a set of mooring lines connecting a floating vessel to the seabed to keep it in position. Traditionally, anchoring of a ship uses one mooring line, but it's not an optimal scheme because the ship is likely to move around the anchor point and oscillate in yaw under the wind and current loads. Researcher proposed a better solution, which is spread mooring. Several mooring lines are connected to different locations of the floating vessel. It can make the ship stay in one direction during the operation time, but on the other hand, it is not very flexible when it comes to the change of vessel yaw angle. Figure 2 illustrates the spread mooring systems on FPSO and semi.

A good solution for mooring systems is turret mooring. All mooring lines connect to what is called a turret, which is located inside or outside the ship. Positioning the turret within the front half of the hull is most commonly used. The mooring lines are then spread into different directions. By this method similar restoring capability in surge and sway can be provided. The turret is usually free to rotate, making the vessel able to move in yaw easily. Being able to rotate the vessel to minimize environmental loads, referred to as weathervaning, is therefore an advantage (Fossen 2011). Figure 3 shows the weathervaning around the turret mooring system.

The first use of mooring systems for position keeping in offshore operations was in 1953 (Fay 1990). But when the development goes into deeper water, the drawbacks become obvious. Then the dynamic positioning system was developed. This idea means the passive mooring system could be replaced by thrusters which can dynamically compensate the environmental loads. However, since DP system requires a large amount of energy during a long working period, the conventional mooring systems still has some economic advantages. So the idea behind thruster-assisted mooring systems is to combine the advantages from both fields, where the mooring system is to withstand the mean environmental loads, while DP system contributes to improve the system dynamic performance that the mooring system is not capable of. For more on automatic thruster-assisted mooring systems, see, for instance, Strand et al. (1998).

In 1961 the vessel CUSS 1 maintained position in an accuracy of 180 m radius with manual controlled thrusters. Later in the same year, a ship named Eureka was equipped with the first computer-based dynamic positioning system. From then on, there has been a steady development of DP systems in all fields related. Kalman filtering and optimal control theory are milestones in the evolution of DP control system. Besides, the researches on hydrodynamics, thrust allocation, and interaction effects all get approaches.

Thruster-Assisted Mooring, Fig. 3 Turret mooring system and weathervaning. (<https://www.bluewater.com/>)

In the 1990s, DP system started to use smarter methods to obtain a better control performance and DP capability. This kind of development was propelled by the demand of a control system which could take both system dynamics and limitations into account at the same time. Model-based design is an advanced method, upon which several functions have been built later. A model-based control system design was presented by Sørensen et al. (1996). The model-based passive nonlinear observer was introduced in Fossen and Strand (1999). The nonlinear passive observer yields global exponential stability. However, the linear Kalman filter theory does not. Strand and Sørensen (2000) proposed a roll and pitch damping controller and proved to damp horizontal motions by exploiting the hydrodynamic couplings between surge and pitch and sway and roll degrees of freedom.

The theory of hybrid control was first implemented in planes and cars. During the course of previous years, hybrid control has also been applied in DP control system. The demand for total system stability, including the switching logic, places special requirements on the DP control system design. Hybrid control is studied in Nguyen and Sørensen (2009b). A hybrid control strategy was proposed by Brodtkorb et al. (2018). This concept allows a structured way to develop a control system with a bank of controllers and observers improving DP performance in stationary

dynamics, changing dynamics including enhancing transient performance, and giving robustness to measurement errors.

Other advanced control methods have also been applied to DP controller design. A Takagi-Sugeno fuzzy dynamic positioning controller was designed for an unmanned marine vehicle in network environments by Wang et al. (2018). Du et al. (2018) proposed a robust adaptive control method for DP ships with unknown model parameters and unknown time-varying disturbances.

The mooring system is a relative low-cost solution. In shallow water and calm weather conditions, mooring systems provide steady station keeping performance for most operations at sea. Dynamic positioning, on the other hand, is a relative high-cost solution compared to passive mooring only. The third option is a merge between mooring and DP. It's the so-called thruster-assisted mooring, position mooring, or DP-assisted mooring. For TAM systems, the mooring lines form a passive elastic system and provide most of the horizontal damping. The thrusters must assist the passive mooring system for environmental loads or operational requirements to obtain an accurate positioning.

Strand et al. (1998) presented the first publication of the combination of thruster assistance and mooring. Position keeping based on adjusting the mooring line lengths using winches was proposed later. Imposing a structural reliability criterion on

riser angles was studied for the floating vessel motion influences the riser dynamic responses. Based on the proposed structural reliability criterion, Berntsen et al. (2006) presented a nonlinear feedback control law by using backstepping techniques. The structural reliability criterion was originally used in the field of construction. Implementation of the algorithms combined with structural reliability consideration could minimize the risk of mooring line failure to a large extent. Thruster-assisted mooring was first merged with hybrid control in Nguyen and Sørensen (2009a). And the hybrid control method is believed to be one of tomorrow's good solutions for both DP and TAM. In Fang et al. (2013), a setpoint chasing method based on mooring line tension was proposed. Reaching the desired setpoint is handled by a control law, e.g., PID.

A DP or TAM system relies on a complex system of different components, as shown in Fig. 4. The key component of the whole system is the control system, which generates thrust command vector given the various input parameters it is provided, as shown in Fig. 5. The most important input information is the vessel position and heading, but in most cases it also receives a variety of other input variables in order to improve control performance, like vessel velocities, wind speed and direction measurements, accelerometer data, and gyro information. The resulting force command is

then passed to a thrust allocation unit, converting it into individual thrust force and direction commands to each thruster. Thrusters on the vessel have their own control system, making sure the right power is applied to the thruster it controls. The power system provides power for other systems of the whole one.

In order to achieve a good estimate of vessel motion, usually it is equipped with multiple motion reference systems. These reference systems are then evaluated to find the most accurate motion estimate. The redundancy configuration is depended on the DP class requirement. Different vessel needs different DP class to hold its position, and it doesn't mean good if each vessel is equipped with the highest class of DP system.

It is necessary to filter the motion signals to obtain a smooth position reference to provide to the control system due to sensor noise and other factors causing inaccuracy. This task is implemented by an observer, which can be, for instance, a Kalman filter or a nonlinear passive observer (Fossen 2011).

The controller can use the accelerometer or wind measurement data for feed forward, meaning it can take advantage of them to predict future position offsets or part of the environmental loads by measuring some of the forces acting on the vessel at the present time. These techniques are however limited by inaccuracy mainly due to

Thruster-Assisted Mooring, Fig. 4 A typical DP system. (<https://www.moxa.com>)

Thruster-Assisted Mooring, Fig. 5 Control system. (https://en.wikipedia.org/wiki/Dynamic_positioning)

sensor disturbances. For instance, the significant local variations of the wind lead to inaccuracy of wind load signal.

In addition to the filtered sensor measurements, the controller is provided with a reference position from the DP operator. This is the desired position for the vessel, meaning the position the controller is supposed to keep the vessel as close as possible to.

For TAM systems the position is determined by the mooring, and the control objectives can be a bit different. For more on marine control systems design, see, for instance, Fossen (2011) and Sørensen (2011).

Control Objectives, Model, and Method

The main objective of a DP system is to keep the floating vessel within a certain radius of a target point. DP is used to prevent failure of risers and other drilling equipment; to stay around the operation spot, for instance, lifting, lowering, and installing; or just to prevent from horizontal position offset when idling. Control objectives are different depending on the kind of positioning requirements. Figure 6 illustrates the forces on a DP vessel.

In addition to stabilizing the vessel in position, DP system is desired to provide additional damping forces. These forces could compensate for low-frequency wave loads and oscillations due to wind, current, etc.

For TAM systems, the damping action is a primary part of the control system functionality. Among the whole system, the mooring lines will withstand the mean loads in surge and sway. The elastic behavior of the mooring system is similar to that of a spring. Therefore, it can be simulated with a proportional controller. To control the vessel position, a derivative term is needed, which can be provided by the thrusters activated by the control system.

If the constraint in yaw cannot be provided by the mooring system, the control system will in most cases be used to control the heading angle. It is useful when the offshore operation requires the ship to keep its heading orientation or just to reduce unnecessary accelerations in yaw. In addition to this, an optimal heading angle can also be maintained by the thrusters to compensate environmental loads. Especially for ships that are sensitive to wind and current force direction, there will be a significant difference in resulting loads

Thruster-Assisted**Mooring, Fig. 6**

Forces on a DP vessel. (<https://www.kongsberg.com/>)

when the load is acting in surge or sway. Therefore, it can reduce the mooring line tensions by dynamically chasing the optimal heading for handling the weather.

Another practical feature for a TAM system is mooring line failure detection and compensation. It means that the control system activates thrusters to prevent further damage on the vessel in the case if one mooring line is broken. Mooring line failure can be detected by sensors on the positioning system, and if the control system receives the signal of line breakage, the thrusters can be immediately activated to generate force to cover the broken line with proper thrust and direction. With the interference of thrusters, another line breakage may be prevented, and the operation can be shut down in a safe environment, and everything could be controllable. Line breakage can also be prevented by using the thrusters to produce force to reduce mooring line tensions when the stresses become too high in the case of extreme conditions.

Therefore, a TAM system is mostly used for the control objectives of damping action (surge and sway), heading control, and mooring line failure compensation and prevention.

Commonly there are two kinds of method for modelling a dynamic system in the frame of

control theory, depending on the purpose of the model.

Usually the process plant model is used to describe the system dynamics as accurately as possible. In this model different nonlinear phenomena would be included as well as the disturbances and noises. This model can be used for numerical simulations and analysis of stability and performance. It can also replace model tests of the system (Nguyen and Sorensen 2009a).

Actually, a vessel with mooring system at sea is subjected to different environmental loads. Combining the cable dynamics, the vessel motion itself is complex. In order to study a dynamic system behaves under any condition, a good description of the system is needed. Therefore, the model will be relatively large and complex. There are most likely several nonlinear phenomena that need to be considered at the same time.

A process plant model is therefore not suited for time-domain analytical computations, which means it cannot be used for the design of control system. That is when a control plant model is applied, which is a simplified version of the process plant model. It is less computationally intensive and easier to work with both numerically and analytically.

TAM systems are different from DP systems, whose main purpose is to keep a floating vessel on

a target position by activating the thrusters on the vessel. In calm weather conditions, the thrusters are mainly used to keep the yaw angle of the vessel for a turret moored vessel, whereas the mooring system maintains the vessel position within an allowable region. However, in harsh weather conditions, the thrusters are not only used to maintain vessel orientation but also to compensate environmental loads in order to keep the line tensions of mooring system under safety limits. The mooring system doesn't consume any fuel making it cost-efficient as well.

It can be assumed that a thruster-assisted mooring system consists of a mooring system and a special DP system. The mooring system is a passive system. But the thruster system is active. So many studies on TAM systems are mainly focused on DP control method. It should be pointed out that vessel mass, center of gravity, and velocity always change by time. In addition, the vessel motion is nonlinear considering the loads on the vessel. So, the control system can be regarded as an uncertain nonlinear system. Recently, nonlinear control theories are proposed in order to handle the inherent nonlinear characteristics of the vessel dynamics, for example, the output feedback control, the nonlinear model predictive control, the adaptive fuzzy control, and the adaptive neural network control. A nonlinear control algorithm based on mooring line structural reliability has been presented by Wang et al. (2014) in which the reliability index is used to quantify the failure probability of mooring lines. The reliability index is set as an intrinsic term of the controller function, the mooring system keeps the position of the floating vessel within an allowable region, while thrusters maintain the structural reliability index of mooring lines within allowable limits. The controllers are built according to the backstepping theory. However, backstepping requires repeated differentiation of the virtual control function, which increases the computational cost. This problem can be solved by applying dynamic surface control which uses first-order filtering of the virtual control.

Vessel with TAM system is assumed to be an uncertain nonlinear system. In order to solve the problem, artificial intelligence algorithms can be used, for example, the fuzzy logic method,

artificial neural networks, and fuzzy neural networks. Niu et al. (2017) used the RBF neural networks to make the approximation of the uncertainty in nonlinear pure-feedback switched time-delay systems, and the fuzzy control systems have also been utilized in various nonlinear systems such as stochastic nonstrict-feedback systems, networked control systems, non-Gaussian stochastic distribution control systems, and Takagi-Sugeno fuzzy systems to compensate some of the uncertain nonlinear effects. Chen et al. (2015) presented an adaptive control approach for MIMO robotic systems with unknown control signs and time-varying nonlinearities. The Nussbaum gain technique is used to estimate the unknown actuator directions. However, the difficulty of using this approach is that the Nussbaum gain has been extended from one dimension to multiple dimensions, which makes the controller design and stability analysis more difficult. To solve the problems, Tuo et al. (2018) designed a novel adaptive robust controller for TAM system of the moored FPSO vessel with model uncertainties and unknown control coefficients.

Key Applications

Thruster-assisted mooring systems are applied to anchored FPSOs and semisubmersibles. They can be used to keep vessel position, maintain vessel heading angle, chase the optimal environmental direction, and compensate the dynamic environmental loads or sudden loads due to mooring line failure.

FPSO

An FPSO is usually positioned by mooring lines in deep water. With a turret it can be rotated according to the environment load direction. If the offshore operation needs a fixed vessel heading and position, the TAM system is online. This can be offloading the oil to a shuttle tanker. TAM or PM system allows for larger operating windows and increases structural reliability in extreme conditions, both for spread and turret moored vessels. The mooring system decreases the level of thrust needed, while the thrusters increase position keeping accuracy.

Semisubmersible

Increasingly newly built semisubmersibles are being equipped with advanced mooring systems and some level of thrust capability for improved station keeping ability. The operation modes range from mooring only in relatively shallow water, thruster-assisted mooring in deep water, and DP mode in ultra-deep water conditions.

TAM has been used in the design of station keeping systems for semisubmersibles. The thrusters (or DP) are used for heading and position control and for reducing the mooring load. One of the principal reasons for using TAM is it can reduce overall project costs by reducing the mooring system in terms of either fewer mooring lines or a lighter overall system, especially for deep water projects.

For a TAM system, the thrusters may only be active under relatively severe weather conditions such that therefore the operation and maintenance cost for the DP system could be relatively lower than that of a DP only operation. With exploration and production moving into increasingly deeper water, TAM has become one of the alternative concepts for vessel motion control.

Tidal and Ocean Current Turbines

Pengfei Liu

School of Engineering, Newcastle University,
Newcastle upon Tyne, UK

Introduction

Tides and Currents of Oceans

Over 70% of the Earth is covered by oceans in the world. These oceans are a vast renewable energy

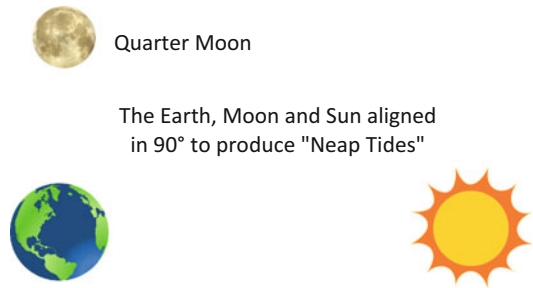

Tidal and Ocean Current Turbines, Fig. 1 Full Moon (New Moon) schematic diagram

source. Energy stored in oceans can be mainly categorized as thermal energy; kinetic energy due to tides, waves and currents; and chemical and biological energies. Tides are caused by planetary motion to produce the flow of seawater. Because the Earth, its Moon, and the Sun rotate around each other, the gravitational movement of the Moon and the Sun with respect to the Earth (see Fig. 1) causes huge amount of water to flow around the Earth's oceans, creating periodic shifts in these moving bodies of water. These vertical shifts of water are called "tides" (Alternative Energy Tutorials 2018).

When the Earth and the Moon's gravity lines up with each other, the influences of these two gravitational forces become very strong and produce a movement of water toward the shore creating a "high tide" condition. When the Moon is in perfect alignment with the Earth and the Sun, the gravitational pull of the Moon and Sun together becomes much stronger than normal with the high tides becoming very high and the low tides becoming very low during each tidal cycle. Such tides are known as spring tides (maximum). These spring tides occur during the Full or New Moon phase.

Similarly, when the Earth and the Moon's gravity are at 90° to each other as shown in Fig. 2, the influences of these two gravitational forces are weaker, and the water flows away from the shore as the mass of water moves to another location on the Earth, creating a "low tide" condition.

This ebbing and flood tides happen twice during each period of rotation of the Earth with stronger weekly and annual lunar cycles superimposed onto these tides. The other tidal situation arises during neap tides (minimum) when the gravitational pull of the Moon and the Sun are against each other, thus cancelling their effects.

Tidal and Ocean Current Turbines, Fig. 2 Quarter Moon when the Earth-Moon and Earth-Sun are aligned in 90°

The net result is a smaller pulling action on the seawater creating much smaller differences between the high and low tides, thereby producing very weak tides. Neap tides occur during the Quarter Moon phase.

The spring tides and neap tides produce different amounts of potential energy in the movement of the seawater as their effects differ from the regular high and low sea levels, and we can use these tidal changes to produce renewable energy. The constant rotational movement of the Earth and the Moon with regard to each other causes huge amounts of water to move around the Earth as the tides go in and out. These tides are predictable and regular resulting in two high tides and two low tides each day with the level of the oceans constantly moving between a high tide and a low tide and then back to a high tide again. The time taken for a tidal cycle to happen is about 12 h and 24 min (called the "diurnal cycle") between two consecutive high tides. The main big advantage of this is that the tides are therefore perfectly predictable and regular unlike wind energy or solar energy, allowing miles of coastline to be used for tidal energy exploitation, and the larger the tidal influence, the greater the movement of the tidal water and therefore the more potential energy that can be harvested for power generation.

Tidal and Current Energy Resources

It is estimated that the total ocean energy reserve in the world is 76 billion kW and the corresponding explorable ocean energy is 15.7 billion kW (Xiang 2010). According to a recent

renewable energy report (Paris: REN21 2017), the total explorable wind power in the world is about 400 TW, and the wind power generation capacity is about 487 GW. Therefore, the wind power utilization rate is extremely small, of about 0.1%. The explorable tidal power in the world is much smaller, about 120 GW, and the tidal power generation capacity about 536 MW, giving a very small utilization rate of 1.2%.

Tidal and Ocean Current Turbines (TOCTs)

The motion of the tidal water, driven by the pull of gravity, contains large amounts of kinetic energy in the form of strong tidal currents called tidal streams. The movement of the seawater can be harnessed in a similar way using waterwheels and turbines to generate hydroelectricity. As the

seawater can flow in both directions in a tidal energy system, it can generate power when the water is flowing in and when it is ebbing out. There are several technologies to harness the kinetic energy from tidal, ocean, and river currents. These are introduced as the following.

Different Types of Tidal and Ocean Current Turbines

Tidal Barrage

Tidal barrage power systems take advantage of the differences between high tides and low tides by using a “barrage,” a type of dam, to block receding water during ebb periods. At low tide, water behind the barrage is released, and the water passes through a turbine that generates electricity. Figure 3 shows the schematic diagram of a tidal barrage.

One disadvantage of tidal barrage generation is that it can only generate electricity when the tide is

Tidal and Ocean Current Turbines,

Fig. 3 Schematic diagram of a tidal barrage (Roberts et al. 2016)

flowing either “in” or “out,” as during high and low tide times the tidal water is stationary. However, because tides are totally predictable, other power stations can compensate for this stationary period when there is no tidal energy being produced. Another disadvantage of a tidal barrage system is the environmental and ecological effects that a long concrete dam may have on the estuaries they span.

Horizontal Axis Tidal Turbine (HATT)

Tidal stream generation is very similar in principal to wind power generation, except this time water currents flow across turbine rotor blades which rotate the turbine, much like how wind turn the blades for wind power turbines. In fact, tidal stream generation areas on the seabed can

look just like underwater wind turbines (Fig. 4).

Tidal generators are designed to produce power when the rotor blades are spinning in both directions. Tidal stream generators use kinetic energy of moving water to power turbines; in tidal stream power generation, some turbines are submerged under the surface of water with sufficient clearance to avoid hazards to navigation and shipping, and some of them are visible on the ocean surface.

To generate power under both ebb and flood tides, tidal currents are designed to work with bi-directional current. Horizontal axis tidal turbines are designed to be either unidirectional or bi-directional. There exist a few descriptions of bi-directional tidal turbines in the open

literature, including the Tocado (1994) and Swan turbines (Orme et al. 2005). The Tocado turbines are designed to have controllable pitch blades to adapt to the inflow direction; their blades' sectional profile is unidirectional. The Swan turbine rotors have bi-directional blade sectional profile. These are all bare rotor blade turbines with no nozzle or duct. Liu and Bose (2012) prototyped a series of bi-directional bladed turbines for the Bay of Fundy. As the rotor blades are fully symmetrical, this series of turbines have the identical performance in either direction, when the inflow conditions are the same. A new optimization theory was established by setting the total energy production as the key criteria rather than the single power coefficient (Liu and Bose 2012). In the study for a 20-m HATT, pitch, pitch distribution, solidity, number of blades at a fixed solidity, etc. were all optimized for the optimum annual energy production under the given probability distribution of the tidal flow speed and corresponding time, in the Minas Passage, the Bay of Fundy, Canada. For a three-bladed 20-m rotor, the optimum p/D and shaft speed n are 0.27 and 0.17 revolution per second, respectively, producing annual renewable energy of 3141 MWh. The averaged constant power production, under the conditions including ebb and flood tides and all absolute speeds lower than the kick-in speed (about 1.3 m/s), is 385 kW. The solidity, or the expanded area ratio (EAR) for optimum power coefficient ($C_{POW} = 0.32$) at an optimum inflow speed for the 20-m bi-directional rotor in Liu and Bose (2012), was validated by a later

Tidal and Ocean Current Turbines,

Fig. 4 Hammerfest Strom HS1000 Turbine in Islay. (Courtesy of the Tethys), Scotland (Annex IV 2018)

Tidal and Ocean Current Turbines, Fig. 5 An optimized bi-directional rotor with optimum solidity of about 0.4. Solidity is the ratio of the projected area of the blade to the area of the circle with the same diameter of the rotor

experimental work (Liu et al. 2014) to be about 0.45. This EAR value is much larger than most of the HATT turbines currently installed, except for the ducted OpenHydro turbines. The rotor with the optimum EAR for the power coefficient is shown in Fig. 5.

Blade failures have dogged the fledgling tidal current turbine industry and have been seriously affecting its apparent viability. Retrieval, salvage, and recovery operations take substantial effort and time, due to poor weather and harsh underwater conditions. Some failures include, for example, blade failure on the OpenHydro 16-m turbine installed in the Bay of Fundy, NS, Canada, on June 11, 2010 (CBC News 2010); blade failure of the two Verdant Power tidal turbines installed in the East River of New York City on December 11, 2006 (Shiekh et al. 2018); and the blade fracture of the Atlantis AR1000 turbine soon after its installation and connection to the grid of the European Marine Energy Centre (EMEC) in August 2010 (BBC News 2010). Failure of rotor blades is due to two main causes: (Allen 2007) the loads are underestimated or unknown, resulting in inadequate design strength, and (Alternative

Tidal and Ocean Current Turbines, Fig. 6 Schematic diagram of a vertical axis water turbine (Roberts et al. 2016)

Energy Tutorials 2018) manufacturing defects result in a much lower strength structure than designed. For these issues, Liu and Veitch (2012) conducted research work concerning blade sectional loading prediction and structural strength design and optimization to meet the strength requirements and save material without sacrificing hydrodynamic performance. For the same required safety factor of 6.51 at 3.1 m/s for the 20-m rotor with the same nickel-aluminum-bronze material, their method saved substantial material, comparing a refined initial design of a blade weight of 229 t with the optimized weight of 143 t, a total of 86 t (37.6%) of saving in material consumption, about \$17M saving at a cost of \$200/kg.

Vertical Axis Tidal Turbine (VATT)

Other forms of tidal energy include tidal fences which use individual vertical-axis turbines that are mounted within a fence structure, known as the caisson, which completely blocks a channel and forces water through them. Figure 6 shows the operation schematic diagram of a vertical axis turbine.

Oscillating Tidal Hydrofoil (OTH)

Another alternative way of harnessing tidal power is to use oscillating foil. The foil pitch, either passively or actively, creates a lift force

and induces the heave motion. The heave motion with force and displacement will create energy. This energy can be transferred to electricity. A schematic diagram for the early prototype of the oscillating foil turbine is shown in Fig. 7.

There are some innovative ideas on oscillating foil turbine. Dumas (Kinsey and Dumas 2012) developed an oscillating foil hydrokinetic turbine (HAO).

Utilizing the wing-in-ground (WIG) effect, Liu (2013) developed a dual-foil counterphase motion WIG turbine (WIGTT). This technology uses an active pitching control to produce arbitrary pitching motion for the highest possible

power production. A two-stage pitching mechanism is shown in Fig. 8.

For a two-stage WIGTT, there are two pairs of foils, and they can be arranged in many different configurations. One of the configurations is for the two pairs in tandem, as shown in Fig. 9.

An extensive numerical study was conducted for the design and optimization of the WIG turbine (Liu 2015). The results showed that the WIG turbine using trapezoidal pitching control motion can produce about 40% more power than sinusoidal pitching control. The counterphase pitching and heaving mechanism-produced WIG effect could further improve more than 30% of power production than two single oscillating foils.

Tidal and Ocean Current Turbines,

Fig. 7 Oscillating hydrofoil tidal turbine (Roberts et al. 2016)

Tidal and Ocean Current Turbines, Fig. 8

A two-stage active arbitrary pitching control mechanism (Liu 2013)

Tidal and Ocean Current Turbines, Fig. 9 WIG oscillating foil turbine in tandem configuration (Liu 2013)

Tidal and Ocean Current Turbines, Fig. 10 Water depth limitation for HATT diameter versus unlimited span of WIG foils

The power generated by a HAT is $P = 0.5 \cdot C_{\text{pow}} \rho V^3 A$, where C_{pow} , ρ , V , and A are power coefficient, fluid density, tidal inflow velocity, and swept area. By letting the swept areas of HATT and WIGTT be equal, i.e., $A_{\text{HATT}} = \pi D^2 / 4 = A_{\text{WIGTT}} = S_{\text{span}} 2h_a$, where S_{span} and h_a are foil span and the heave amplitude of each foil, time-domain unsteady panel methods for the WIGTT and HATT were applied to predict the power generation performance of a 20-m HATT and WIGTT foil turbine, respectively. The WIGTT produced over 70% more power than the HATT. One of the foils of the dual-foil WIG effect turbine also produced over 1.85 times of a single foil turbine for the same pitching motion without WIG effect.

Why WIG Effect Turbine: The Pros and Cons Based on the results, the advantages

and disadvantages of the WIG effect tidal turbine were listed as the following (Liu 2015):

The pros of the WIG effect turbine:

- High energy production performance, about 1.7 times of HAT with the same swept area
- High power capacity with confined water depth (see Fig. 10)

When the depth, and hence the HATT diameter, is a constraint, to increase energy production by ten times with the same water depth, 10 HATTs will be required to form a farm configuration, but for WIGTT with the same depth, it would need only to extend the span by ten times.

- Less impact on ecology. The maximum velocity at the 20-m HATT rotor tip (Liu and Bose 2012) is $V_{\text{tip}} = \pi D n = 20 \pi 0.17 = 10.68 \text{ m/s}$,

but for the foil of the WIGTT, it is $V_{\text{foil}} = h_{\text{amp}} \omega = 4 * 0.5 = 2.00$ m/s. WIGTT therefore has the following environmental advantages:

- (I) With 1/5 of the motion speed of HATTs, they have much less flow disturbance on surroundings.
- (II) With less than 2 m/s foil motion speed, they are unlikely to threaten/damage most marine creatures in ocean.
- (III) WIGTT foils have wavy flow downstream but no rotation induced by HAT rotors.
- (IV) Having a slower foil motion, WIGTTs operate more quietly.
- Safer operation and better hydrodynamic characteristics. WIGTT has the following benefits for design, maintenance, installation, and operation:
 - (I) Much simpler blade/foil structure – less chances of break-off and fracture of foils/blades than HATTs
 - (II) Less prone to tangling with fishing nets, etc., due to much slower and linear foil motion
 - (III) Less prone to collision damage with debris, ice blocks, wood logs, etc.
 - (IV) Lower requirement on structure strength
 - (V) More even velocity and hence pressure and load distribution on blade/foil, hence less prone to cavitation and its related damage in shallow waters and fast flow sites
 - (VI) Low kick-in speed: 0.5 m/s found in this study versus 1.3 m/s for HATT, applicable for much wide range of flow speeds

The cons of the WIG effect turbine:

- Power is required for pitch control. As mentioned earlier the pitch control consumes power. However, power consumption is only a small portion of the total energy generation. For the optimum ω of about 0.5 rad/sec, pitch control power consumption is about 10% and 2% for trapezoidal and sinusoidal pitch motions, respectively.
- Crankshaft or linear generator. For traditional generator/alternator, WIGTT requires motion

translation from heave to rotation, unless linear generator/alternator is used. Linear generator would eliminate efficiency loss in motion translation.

Vortex-Induced Vibrating Tidal Cylinders (VIVTT)

The technology idea of a bluff body energy converter was originated by Allen (2007). In the technology, a power generating system comprises a bluff (non-streamlined) body placed in a fluid stream at 90° to the flow direction for creating a von Karman vortex street behind the body. The bluff body oscillatory movements are coupled to and energize a power generator. An impedance matching system is employed for electrically varying the natural frequency characteristics of the bluff body such that, over a relatively wide range of fluid flow velocities, the bluff body oscillates at a resonant frequency of the body for maximum energy transfer from the fluid stream to the bluff body. An enhancement to bluff body energy converter technology was patented by Bernitsas et al. (2008), the vortex-induced vibration aquatic clean energy (VIVACE) converter. This study showed that the VIVACE is suitable for slow inflow current, as slow as 0.2 m/sec.

Comparison of Tidal Energy Between Ocean Tidal and Wave Technologies

Tidal energy generation technologies have many advantages compared to other forms of renewable energy. The main advantage is that it is predictable. The following table shows the comparison among the three kinds of renewable technologies.

Table 1 shows that the total explorable ocean wave energy is huge, but because of its low energy density, high cost, and no predictability, there is little completed for the development in wave energy capacity. The total explorable tidal energy is high, though much lower than the wave. The exploration rate of tidal energy is still very low, and most of the installed capacity is contributed by the tidal barrage, which has little room for more. This means that the tidal turbine technology development should be the strategic direction of the ocean tidal energy development.

According to World Energy Council (2016), today about 0.6 GW of commercial ocean energy

Tidal and Ocean Current Turbines, Table 1 Comparison of tidal and wave energy technologies

Recourses	Explorable globally (GW)	Capacity globally (GW)	Energy density	Predictability and stability	Visual impact	Building cost	Operation cost
Wave	3,368,000	0.56	Low	No	Bad	Very high	Very high
Tidal	137000	22	High	Very good	Good	High	High

generation capacity is in operation and another 1.7 GW under construction, with 99% of this accounted for by tidal energy. While relatively few commercial-scale wave, tidal stream projects are operational, there are three tidal stream commercial projects accounting for 17 MW of capacity (two in Scotland and one in France).

Tidal Energy Summary

Because of the predictability and hence the advantage of the reduction of fluctuation of the power grid and the density of the tidal energy, along with several other advantages, tidal energy technologies have experienced the fastest development in the ocean renewable energy industries. Currently the tidal barrage is still the biggest contributor to ocean tidal energy, but the tidal turbine development becomes more and more important strategic development.

The two main issues that hinder the development of tidal turbines are (1) the investment/cost of the manufacture and installation and (2) the utilization of the lower tidal flow speed. With the technology development in tidal turbines, these two issues are being gradually resolved. With the recent development of some novel technologies, for example, the WIGTTs, have much lower environmental impact to both flora and fauna, much lower kick-in speed (0.5 m/s vs. 1.3 m/s for HATTs) of which avails the possibility for rivers of low speed current, much higher power production efficiency, and shallow water applicability, etc. These novel technologies will eventually be at least an alternative or substitutes to traditional HATTs. There have had great establishment and progress in ocean tidal and current turbines, and these technologies proved their promising roles in the ocean renewable energy

stage, though there are still some challenges and issues to be met and addressed.

Definition

Towing tank tests are tests performed in a towing tank with ship and offshore structure models or submarine and submersible models which include powering performance tests, maneuvering test, seakeeping test, water flow field measurement, and so on, which are the most important and basic parts of ship model tests. Surface ship models, underwater vehicles such as submarine, submersible, torpedo, Autonomous Underwater Vehicle (AUV), Remotely Operated Vehicle (ROV), and so on, amphibious vehicles such as military amphibious tanks for marine troops or even aircrafts used such as wing-in-ground-effect ships, or amphibious aircraft could carry out towing tank model tests. The model tests can be carried out under different environments, such as calm water, various kinds of waves with different height and frequency, or wind. The model, either floating on the water surface or submerged in the water, is usually towed by a device connected with the carriage during the test. The carriage runs on two rails for different speed. Forces or motions are measured. Towing tank tests were the earliest model tests that people carried out, and nowadays they have taken the largest share among all kinds of ship model tests. So when people talk about ship model tests or tank tests, they are talking about towing tank tests in fact (https://en.wikipedia.org/wiki/towing_tank_tests).

Scientific Fundamentals

Towing Test Types

A division of various towing tank tests is given in Fig. 1. These include powering performance test, seakeeping test, maneuvering test, and other tests. Powering performance tests include resistance test, propeller open water test, and self-propulsion tests. Other tests include 3D wake measurement and flow visualization tests.

1. Resistance Tests

It is the hull resistance when the ship or water vehicle moves in the water at a speed or if there is water flow around (ITTC 1990a). The force measurement for the water flow that loaded on the vessel is carried out in the same way with the resistance tests. Usually, hull resistance is measured at increasing speeds in order to develop a curve for the vessel at specific condition, one or several displacements, or trim angles. For surface ships, the model tests are carried out mainly in moving-forward direction. However, for underwater vehicles, there will be resistance for several directions, which could be moving forward, backward in the horizontal plane, moving upward and downward in the vertical plane, and at last, moving transverse. Usually the trim angle and the sinkage of ships will be measured during the resistance tests.

Towing Tank Test,
Fig. 1 A division of
various towing tank tests

2. Propeller Open Water Tests

Propeller open water test is the propeller performance test without anything in front; this is why it is called open water. By carrying out this kind of tests, people will know the performance of the propeller, which is the most popular thruster for ships and underwater vehicles. The test data will be recorded by thrust coefficient, torque coefficient, and efficiency.

3. Self-Propulsion Tests

The ship or vessel, the propellers, and motor, three parts of a full-scale ship that can run on the sea, are put together in self-propulsion test. The thrust and torque of the propellers will be measured. The rotation of the propeller is usually settled according to the test plan. Several speeds will be carefully chosen, which are close to the design speed (ITTC 1990b). The speed of the design ship and the rotation of propeller will be predicted with the test data including the hull resistance tests and propeller open water tests all together. These kind of tests are very important for most ships, merchant ships, or navy ships, both surface warships and submarine and torpedoes, which are sensitive to fuel consumption or top speed. However, there are few cases for underwater vehicles models self-propulsion tests. Manned submersibles or Remotely Operated Vehicles (ROV) are not very sensitive to speed or energy consumption. For other underwater vehicles, they are not very big so it will be easier to carry out full-scale tests, not the scaled model tests.

4. Seakeeping Tests

Seakeeping tests are done to evaluate the behaviors of the ships or vessel in waves. In towing tank tests, the waves are ahead at sea or following. Usually the model can be self-propelled or towed with tethered spring. The heave, rolling, pitch, and accelerations will be measured during the tests compared with the wave data. When underwater vehicles are during the launch or recovery process, the waves will have great effect. However, the seakeeping ability is not as important as other performance, in fact, and the designers will not refine

or change the design too much to make the sub better seakeeping.

5. 3D Wake Measurement Tests

The water flow around the propeller is called the wake of the ship. Usually the water data is measured in a round circle with a diameter 20% larger than that of the propeller. Five holes Pitot tubes are tools, and nowadays, 3D Particle Image Velocimetry (PIV) technology is developed and applied more and more.

6. Flow Visualization Tests

For determining the flow pattern along the hull, various flow visualization techniques are available. Paint method or tuft with underwater videography is mainly used, and PIV can be useful and helpful by recording several sections along the ship. In this way, the flow field around the ship can be recorded.

7. Maneuvering Tests

There are usually two kinds of maneuvering tests, free running model tests and captive model tests. As the towing tank is narrow compared to its length, captive model tests are more often carried out. During captive model tests, the model will be fixed in several conditions, different trim angles or rudder angles, for example. The force and moment of the model will be measured. Planar Motion Mechanism (PMM) is an important device for maneuvering tests. Hydrodynamic derivatives in the maneuvering mathematic models can be calculated by using the test data.

Historical Development

It is believed that W. Froude built the first towing tank in the world in Torquay for the Britain Navy Admiralty in 1871. Since then, towing tank tests have been carried out for more than 100 years. More than 150 towing tanks have been built in the world and tens of thousands towing tank tests are carried out every year.

David Taylor Towing Tank was built in Maryland in America. It is still the largest towing tank in the world. See Fig. 2, the photo of David Taylor Towing Tank, which was taken in 1940 after the tank was built. David Taylor himself is seen in Fig. 2. The tank is divided into three parts, a shallow towing tank, a deepwater towing tank,

Towing Tank Test, Fig. 2 David Taylor Towing Tank (on the left side) and David Taylor (on the right side)

and a high-speed towing tank. Research studies on large merchant ships, war ships, and submarines have been carried out ever since 1940, the year it was finished. Powering performance and seakeeping abilities model tests support the navy, coast guard, and offshore projects. Advance carriage, wave makers, and measurement devices make it possible to carry out a model as large as 40 feet long and bias less than 2%.

In China, the first towing tank was built in Shanghai in 1854. It was 70 m long. Then in 1965, a larger towing tank was built in Wuxi by China Ship Scientific Research Centre (CSSRC), 474 m long, 14 m wide, and 7 m deep, shown in Fig. 3. It is one of top three largest three towing tanks in the world (the other in USA and in Russia), and in 2022, it will be enlarged to 1108 m long. CSSRC built a depressurized towing tank in 1985, which is 150 m long, 7 m wide, and 5 m deep, as shown in Fig. 4. The air pressure inside can be decreased to as low as 5% of atmospheric pressure.

The Maritime Research Institute Netherlands was founded in 1929 as the Netherlands Ship Model Basin (NSMB) by the Dutch government and industry. Work was started in 1932, following completion of the deepwater towing tank. To cope with the ever-increasing demands of the industry for research in the fields of powering

performance, seakeeping, and maneuvering, including shallow water effects, cavitation, vibration, noise, etc., a whole series of special test laboratories were successively built (Deep Water Towing Tank 1951, Shallow Water Basin 1958, High Speed Basin 1965, Depressurized Towing Tank 1972, and Cavitation tunnel 1979). A new seakeeping and maneuvering basin became operational in the course of 1999. The upgrading of the depressurized towing tank into an depressurized wave basin was completed in 2012. In 2015, the high speed basin was rebuilt into a concept basin.

MARIN owns four towing tanks, including the deepwater towing tank, the depressurized wave basin, the shallow water basin, and the concept basin. Here the word Basin is equal to the word Tank.

The deepwater towing tank ($252 \times 10.5 \times 5.5$ m) is used to optimize resistance and propulsion characteristics of ship designs. To provide insight in the possible improvements in performance, the tank has the features to measure various wave and flow patterns. In addition to the standard resistance and propulsion tests, the rudder or pod angle, pod position, and propeller rotation direction can be optimized.

The depressurized wave basin ($240 \times 18 \times 8$ m) is a unique research facility for testing ships and offshore structures in the most realistic

Towing Tank Test,**Fig. 3** Deepwater towing tank in CSSRC**Towing Tank Test,****Fig. 4** Depressurized towing tank in CSSRC

operational conditions. The basin is fitted with wave generators, and the air pressure in the basin can be decreased to as low as 2.5% of atmospheric pressure. This way many important research aspects concerning cavitation, wave forces, flooding, and seakeeping can be studied using a properly-scaled condition for both water and air.

The depth of the shallow water basin (220×15.75 m) is adjustable from 0 to 1.15 m. It is used to optimize the propulsion characteristics of ships as well as the (low speed) maneuvering behavior in shallow water. This includes

factors such as proximity of quays and bank suction. The test can be used as input for simulations which help to optimize nautical strategies. The facility is also used for concept development and design support of new offshore designs in shallow water.

The concept basin has a length of 220 m, a width of 4 m, and a depth of 3.6 m. The basin is filled with fresh water. It is mainly designed to perform calm water and seakeeping model tests of ships and structures in the concept phase. Furthermore, the basin can be used for research purposes.

Key Technology in Carrying Out a Towing Tank Test

There are six elements for successful towing tank tests. They are the tank, the model, model speed, turbulence, measurement, and prediction.

1. The Tank

The tank should be built in a good environment where there is no heavy traffic, far from smoke and air pollution. The foundation should be solid and firm, for example, bedrock. At last, there should be fresh water supply nearby.

The tank should be large enough for the model. The cross-section area of ship models should be less than 0.5% of the tank. It is suggested to build the tank as long as possible, for more stable water flow around the ship model and safer for the carriage when speed decreases.

2. The Model

The model ship and the full-scale ship are geometrically similar. The model should be manufactured with high precision, and there are rudders or fins, which should be manufactured and installed to the ship model (Townsin 1990). Sometimes they are too small to be well manufactured. In other cases,

manipulators, for example, are usually too complex to be manufactured. The model is simplified in most cases. How to simplify the model should be recorded.

Careful attention should be paid to the roughness of the model skin. Usually the models are painted with some standard methods (Candries 2001).

3. Model Speed

During the tests, the model will be towed by the carriage. So the model speed is the carriage speed unless the centerline of the model is not parallel to the centerline of the running carriage. There is a towing system on the carriage including a towing pole and two towing guide poles, one is close to the stern and the other one is near the bow. The centerline of the towing system should be in the ship model centerline, which should be parallel to the centerline of the running carriage. The carriage runs on two rails, which should be parallel to each other, and the levelness and straightness of each rail should accord with the design and specifications.

The rotation control of the carriage motors and the diameters of each wheel should be checked. There is also a high standard for the speed control system.

Towing Tank Test,
Fig. 5 Open water
dynamometer

During the tests, the model speed is obviously not that of the full-scale ship. There is relation between them. For surface ships, the Froude Law is applied. In this case, the model speed $V_M = V_S/\sqrt{\lambda}$. Here, V_M is the model speed, V_S is the full-scale ship speed, and λ is the scale factor between the model and the ship.

4. Turbulence

The model is much smaller than the full-scale ship. In the hydrodynamic view, the model has a much smaller Reynolds number than the full-scale ship. Turbulence will be quite different near the model and in the

boundary layer, where it is more important. For example, there will be more laminar flow covering the model much larger than that of the full-scale ship. Then, the friction resistance could not be calculated in a scientific way. The laminar flow and turbulence flow perform quite differently from each other. Take the flow around a cylinder as an example, and there will be a lot of separation vortex for turbulence and much less for laminar flow.

Small wires or nails have been used to be turbulence stimulators on the model, which will stimulate the laminar to be turbulent. It's important where to fix them and how much.

Towing Tank Test, Fig. 6 Deep water towing tank in MARIN

5. Measurement

There are hull resistance devices to measure hull resistance, open water dynamometers for propeller open water tests, and self-propulsion dynamometers for self-propulsion tests. The devices are specially designed and should be regularly checked. See Fig. 5, a propeller model made of copper alloy was fixed in the front of a shaft, which is one part of the open water dynamometer. When the carriage started, the moving water would hit the propeller model without hitting other device or installation. This is why these tests are called open water.

6. Prediction

There is always bias between the model data and the full-scale ship performance. Scale effects play the most important role. The water flow between the model and the full-scale ship is always different even we have

already manufactured similar model and fixed turbulence stimulators (ITTC 2002). Hydrodynamic perform different for different scale and dimensions, which is called scale effect. There is no scientific method to solve the problem. However, many engineered methods have been developed. Friction allowance coefficient is widely applied today, based on thousands of samples between towing tank tests and full-scale ship sea trails (Townsin et al. 1984).

Key Applications

1. Deep Water Towing Tank in MARIN

The deep water towing tank in MARIN is not the largest in the world, but it is a representative tank.

Towing Tank Test,
Fig. 7 The model of
7000m Jialong Sub

Towing Tank Test,
Fig. 8 Towing tank tests
(forward resistance tests)
($\alpha = 0^\circ$)

The tank is 250 m long, as shown in Fig. 6. There were wave makers on the end of the tank, which were removed.

Resistance and self-propulsion tests, open water tests of various types of propulsor (open or ducted propeller), 3-D wake surveys, measurement of hydrodynamic forces and moments on submerged bodies, foils, etc., flow observation tests by 3D Particle Image Velocimetry (3D-PIV), paint or tufts, vertical/horizontal planar motion measurements, and longitudinal wave cut experiments.

2. 7000m Jiaolong Submodel Towing Tank Tests

The 7000m Jiaolong Sub has carried a lot of model tests during different design periods, shown in Fig. 7. Towing tank tests played an important role, as shown in Fig. 8.

[Fish cage](#); [Long-line aquaculture](#); [Mussel farm](#); [Offshore fish farm](#)

Definition

To satisfy the increasing demand for fishery products, net cage and raft facilities have been developed to raise fish and shellfish. A net cage is a kind of structure that mainly consists of a floating collar, a net, sinkers, and mooring lines. According to its operation performance, net cages can be divided into four types: gravity net cages, floating rope cages, spar sea stations, and tension-leg cages. Raft aquaculture systems are easy to operate and can be used to realize the culture of scallops, oysters, mussels, algae, and other species; consequently, the use of such systems has rapidly expanded in numerous countries.

Development History and Classification

The global demand for fishery products is becoming increasingly severe as the world's population expands and wild fish stocks decline. Marine aquaculture is expanding all over the world, and net cages and raft aquaculture systems are becoming prevalent in the aquaculture industry to satisfy the increasing need for sea food.

Traditional Net Cage Development History

According to records, cage culture began in Cambodia, with a history of more than 100 years. Japan initially began to examine wave-resistant net cages, and by the end of the 1980s, Japan

Traditional Aquaculture Structures, Fig. 1 Picture of a gravity net cage (Bi et al. 2020a)

had developed a large offshore net cage system. At present, Norway is at the forefront of offshore net cage development.

Traditional Net Cage Classification

Gravity Net Cage

Norway is a major producer of gravity cages. Gravity cages occupy a large share of the net cage market due to their superior anti-wave performance and convenient daily management and maintenance. China introduced gravity cages and started independent research and development in 1998.

The gravity cage is mainly composed of a floating system, net, counterweight system, and mooring system (Fig. 1). Floating systems are generally composed of two or three rows of high-density polyethylene floating pipes bent into circular or square frames. The floating pipe diameter is generally 200–300 mm. The diameter of the floating system depends on the size of the net cage. Floating systems appear in many different sizes, although they usually tend to be extremely large. The floating system provides buoyancy for the cage and supports the net system, which is mainly used to maintain the aquaculture water body, prevent fish from escaping, and prevent enemy invasion. Therefore, single- or double-layer net systems are adopted in practical applications. The net system is generally made of

polyethylene or nylon material. To reduce friction damage to fish, the mesh is often woven into a non-nodular configuration. The size of the mesh depends on the size and varieties of the fish. A net system that is directly linked to a float collar is generally designed to be cylindrical. The counterweight system considerably influences the hydrodynamic characteristics of the gravity cage and deformation of the net. The mooring system fixes the net cage in the designated area and limits the drift of the net cage.

Floating Rope Cage

Floating rope cages first appeared in Japan and consisted of ropes, boxes, floaters, etc. (Fig. 2). Because of the flexible floating system, the entire net cage can move with the waves, thereby enhancing the anti-wave performance. In addition, the cage is a kind of six-sided closed box body, which prevents it from being damaged by winds and waves and prevents the fish from escaping.

Spar Sea Station

A spar sea station is mainly composed of the frame body and mooring system (Fig. 3). The frame mainly includes the working platform, center column, pendant, net bag, wire rope, and inflation system. In China, spar sea stations are enhanced in terms of two aspects, specifically, the center column and working platform. The

Traditional Aquaculture Structures, Fig. 2 Picture of a floating rope cage

Traditional Aquaculture Structures, Fig. 3 Picture of a spar sea station (Xu and Qin 2020)

greatest innovation is that the working platform can slide along the column, and the floating state of the cage can be adjusted. Owing to these enhancements, spar sea stations are easy to clean; moreover, the net bag can be conveniently checked, and it is easy to catch and classify the fish.

The particularity of the spar sea station determines its specific characteristics. Spar sea stations can resist the effects of 5–10 m high waves. Moreover, such stations have a small volume loss rate, long service life, large net change period, and low cost. Furthermore, spar sea stations can be dragged as one unit, thereby effectively avoiding the effects of red tides. Due to their excellent anti-wind and anti-current performance, spar sea stations have emerged as the primary choice for aquaculture in sea regions characterized by large water depths and wave heights. However, such cages also suffer from a fatal weakness.

Compared with gravity cages, spar sea stations are extremely large, and as a result, their effective aquaculture volume is only one-third of that of a gravity cage having the same height and diameter. This disadvantage limits the operation management; moreover, additional ancillary facilities and professional management personnel are needed, which results in a cost increase.

Tension-Leg Cage

Tension-leg cages (Fig. 4), which exhibit high wind and wave resistance, represent one of Norway's main cage products. A tension-leg cage is composed of jar-shaped cages, tension legs, and mooring blocks in three parts. The jar-shaped cages are the main body for fish breeding and adult fishing. The tension legs are usually extensible ropes that tie the net to the mooring blocks. The mooring blocks are fixed on the bottom of the sea to set the shape of the net.

Traditional Aquaculture Structures, Fig. 4 Picture of a tension-leg cage. (Picture from http://refamed.com/gabbie_mare/tlc_system.html)

(c) semi-submersible rigid fish farm, Ocean Farm 1; and (d) semi-submersible spar fish farm concept (Xu and Qin 2020)

Novel Platforms

In recent years, many large offshore fish farms such as vessel-shaped, semi-submersible rigid fish farm and semi-submersible spar fish farm

have achieved a satisfactory performance in terms of current and wave resistance. Figure 5 shows photos of several new fish farming facilities among many others.

Raft Culture Development History

Raft structures are mostly concentrated in coastal waters. Due to the excessively high breeding density, marine pollution, and deficiency of nutrition in coastal waters, which result in the high mortality of shellfish in shallow seas, it is imperative for long-line aquaculture to be developed toward the open sea to expand the breeding space. However, without the protection of the bay, intense sea conditions pose a considerable challenge to the safety of offshore aquaculture facilities. Scholars have adopted various methods to optimize the structural design to resist wind and waves. Chile and New Zealand are some of the main countries using raft facilities to breed mussels. In China, raft facilities are mainly used to cultivate kelp, wakame, stone cauliflower, mussels, and scallops.

Raft Culture Classification

The raft culture framework is mainly used to culture shellfish (scallops, oysters, abalone) and algae (kelp, nori). Raft facilities have two main forms: sleeves and lantern nets. Sleeves are mainly used to realize the aquaculture of algae

and mussels; lantern nets are used to culture several kinds of shellfish (Fig. 6).

According to their different buoyancy systems, raft facilities can be divided into long-line structures and HDPE tube structures.

Long-Line Aquaculture Facilities

Long-line aquaculture facilities represent a form of raft farming that is generally adopted in the industrial aquaculture of shellfish and algae. Each long line consists of two parallel backbone ropes supported by buoys spaced a few meters apart (Fig. 7).

HDPE Tube Aquaculture Facility

This kind of long-line aquaculture facility uses high-density polyethylene (HDPE) tubes as the buoyancy system. Several studies have demonstrated that long-line HDPE tubes are highly stable under wave action, which facilitates the growth of products.

According to the position of the buoyancy system, it can be divided into two types: a floating type and submerged type (Fig. 8).

Traditional Aquaculture Structures,

Sleeves for Mussel

Sleeves for Alga

Sleeves for Shellfish

Traditional Aquaculture Structures,

Fig. 7 Sketches of a New Zealand-style long-line mussel farm: (a) elevation mooring lines are usually aligned approximately 25° from the horizontal; (b) plan view of a block of long lines that may contain as many as 15 individual long lines; and (c) small section of a long-line system showing floats, backbone ropes, and stocked line droppers (Stevens et al. 2008)

Floating Type

The buoyancy system floats on water and is thus suitable for calm sea areas. This structure is easy to manage and harvest.

Submerged Type

The submerged raft structure carries the buoyancy system to a certain depth below the surface. In this manner, the structure can avoid the damage caused by strong winds and waves and remain stable. Such structures are suitable for rough sea conditions, although management and harvesting are difficult.

Development Trend

Traditional net cage culture and raft culture systems can only be arranged in shallow bays. These structures are vulnerable to terrestrial pollution

and exhibit inferior wind and wave resistance. Moreover, the organisms attached to the net affect the water exchange, and the residual bait cannot be discharged in time. All these issues lead to the frequent occurrence of diseases and deterioration of the product quality. In addition, the marine environment near the shore is polluted, which limits the supply of coastal waters for use. Consequently, the marine aquaculture industry has been forced to move farther into the sea.

Compared with traditional offshore aquaculture structures, offshore aquaculture facilities are characterized by a large capacity, high yield, and high efficiency and are ecologically friendly. Such structures represent an advanced mode of the rational development and utilization of marine fishery resources. As offshore aquaculture structures are located in deeper waters, they are

Traditional Aquaculture Structures,

Fig. 8 Sketches of (a) floating-type and (b) submerged-type systems (Stevens et al. 2008)

subjected to environmental loads caused by adverse sea conditions. The design of their net cages and raft structures is closely related to their hydrodynamic characteristics. The simulation of the hydrodynamic response is extremely complex and challenging, involving multiple disciplines such as hydrodynamics, structural mechanics, soil mechanics, and ethology. Researchers have conducted extensive research through theoretical analyses, physical model tests, numerical simulations, and even field prototype observations.

Research Focus

Net Cage

Biofouling

Biofouling is a phenomenon involving the accumulation of marine organisms (Fig. 9), which can lead to rapid occlusion of the netting mesh (Braithwaite et al. 2007). Biofouling communities

act as disease reservoirs and can increase the risk to farmed fish (Fitridge et al. 2012). Moreover, the hydrodynamic forces acting on the net cage are dramatically increased, thereby increasing the risk of structural failure and fatigue damage (Klebert et al. 2013). Biofouled netting may easily deform in currents, thereby detrimentally affecting the effective volume of farmed fish. In addition, the attenuation of currents through the net cage increases, which decreases the water exchange and oxygen supply inside the net cage (Bi et al. 2015). In addition, the motion responses, geometric deformation, dynamic forces, and flow fields regarding the net cage are important for both the design and the maintenance of offshore aquaculture facilities. Thus, investigating the hydrodynamic characteristics of biofouled nets is of significance for aquaculture engineering. In recent decades, a large number of studies have been carried out to investigate the effects of biofouling on the hydrodynamic characteristics of the net structure (Swift et al. 2006; Gansel et al. 2015; Bi et al. 2018).

Traditional Aquaculture Structures, Fig. 9 Sketch of the net cage (left) and photo of a biofouled net (right) (Bi et al. 2018)

Design of Mooring System

The design factors of mooring systems considerably influence the hydrodynamic characteristics of marine structures. Huang and Pan (2010) and DeCew et al. (2010) studied the hydrodynamic behaviors of net cages with different mooring systems for reference. Single-point mooring, grid array, and fixed multipoint mooring arrangements have been considered for net cages. The mooring scope should be considered in the design of a mooring system to avoid collision or entanglement with other components (DeCew et al. 2010).

Flow Reduction

In the open ocean, fluid flows through the net cage and raft structure, and the motion of the flow is highly complex. A net is a kind of small-scale flexible structure. The interaction between the net and fluid is highly complicated. Although the hydrodynamics of the fishing net have been extensively examined, the behaviors of the fluid flowing around a fishing net and velocity reduction downstream of a fishing net remain problems to be solved. These mechanisms have been typically investigated using scaled physical and numerical models and, where possible, field measurements. From both engineering and ecological perspectives, the flow field of open-ocean aquaculture net cages under the effect of steady ocean currents must be considered. Aarsnes et al. (1990) carried out a series of tests to study the velocity

distribution within net cage systems and developed velocity reduction formulas for the net cages. Fredriksson (2001) studied the flow velocity in an open ocean cage through field measurements and observed that the velocity was reduced by 10%. Lader et al. (2003) conducted a series of experiments to investigate the forces and geometry of a net cage in uniform flow and measured an average velocity reduction of 20% inside the cage. Johansson et al. (2007) performed field measurements at four farms in Norway and observed a considerable reduction (33–64%) in the current passing through the cages. Gansel et al. (2012) conducted laboratory tests and field measurements to study the effects of biofouling and fish behavior on the flow field inside and around stocked salmon fish cages. More recently, Bi et al. (2014) developed a numerical strategy to study the flow inside and around flexible fish cages by combining the porous-media fluid model and the lumped-mass mechanical model based on the work of Zhao et al. (2013). Rasmussen et al. (2015) conducted full-scale measurements to visualize the flow field in the wake of a salmon farm.

Net Material

Traditionally, net chambers are composed of nylon netting. However, potential improvements in fish farming operations and maintenance can be achieved by substituting polymer nets with copper

a

b

Traditional Aquaculture Structures, Fig. 10 Photographs of a fish cage after 7 months of deployment in the North Atlantic. (a) Image of copper netting in the ocean

with a section of biofouled nylon netting; (b) heavily fouled diver door made of nylon (Tsukrov et al. 2011)

alloy netting. In particular, copper nets demonstrate excellent resistance to corrosion and biofouling (Tsukrov et al. 2011), the potential to protect fish against predator attacks and increased structural integrity and stability of the net structure volume under extreme weather conditions. The effectiveness of the biofouling resistance of copper netting is illustrated in Fig. 10.

Numerical Method

As a kind of flexible structure, a net produces large deformations under the action of marine environmental loads. Therefore, research on the hydrodynamics of the whole structure is focused on net deformation.

One of the primary engineering problems to be solved is the design of aquaculture structures built to withstand the environmental loads of the open ocean. These loads are commonly due to water currents and surface waves. The design process often relies heavily upon the use of physical model tests in wave/tow basin facilities. Recently, numerical models have been developed and applied specifically for open ocean aquaculture applications. Most of these models adopt the finite element analysis (FEA) and lumped mass method with the Morison equation formulation to calculate the loads due to currents and waves (Zhao et al. 2010). Tsukrov et al.

(2003) proposed the concept of consistent finite elements and introduced nonlinear elements to optimize the numerical model to calculate the hydrodynamic response of the net panel. Some researchers also used ABAQUSTM with the ABAQUS/Aqua model. Kristiansen and Faltinsen (2012) applied a screen type of force model to investigate the current loads on the fish cage.

To calculate the current field, because a net can be approximated by many small cylinders connected with knots, Patursson et al. (2010) and Zhao et al. (2013) proposed an approach to simulate the net as a thin volume of porous media to analyze the flow field around the net cage structure. In this approach, the net cage is modeled as a porous membrane with a finite thickness over which the total pressure drop in the incoming current is defined by a combination of Darcy's law and an additional term accounting for the inertial effects. Although a series of studies were conducted on the flow field inside and outside the net structure, the details of the flow field around each net mesh have not been clarified. Notably, the numerical simulation of the flow field around a stocked net cage is complex due to the innumerable meshes and other properties, such as the boundary conditions of the fish skin and structural flexibility.

Fish Behavior

The presence of fish occupies up to 2.5% of the volume, which influences the flow through the internal structure as well as the hydrodynamic loads (He et al. 2018). Experimental and CFD methods have been used to predict the influence of fish behavior on aquaculture facilities (Johansson et al. 2014; He et al. 2018; Bi et al. 2020b).

Raft Aquaculture

Factors Influencing Product Growth

A greater oxygen exchange and higher stable water temperatures can accelerate the growth of scallops (Jensen et al. 2007). However, certain studies have highlighted the negative effect of the movement of suspended enclosures introduced by wave actions on the growth of scallops (Freites et al. 1999). Strong wave exposure and movement of the structure may lead to the increased allocation of energy to body maintenance and production of skeletal structures, leaving a reduced amount of energy for growth (Kingzett and Bourne 1991).

Design Factors

The design of the raft structure, such as the component materials and space of individual sleeves, also effect growth (Díaz et al. 2011). The difference in growth can be attributed to the amplitude of structural motion, as calm structures result in a high yield. Wood blocks, rubber tubing, and small-floater surface buoys can be used to minimize the effect of shaking caused by wave action.

Arrangement

Submerged raft structures exhibit a higher resistance to waves and current conditions, thereby rendering the structures less vulnerable to structural damage, deformation, and abrasion and achieving high survival rates by producing individuals of a higher quality (Lee et al. 2009). Furthermore, the harmful effects of toxic algal blooms can be avoided in this configuration. Increasing the depth of lantern nets, although not to the point at which growth is limited by the

lower temperatures and decreased food abundance, is another strategy to reduce fouling and limit competing organisms (Lodeiros and Himmelman 1996). The configuration and culture depth may lead to differences in food production (Emerson et al. 1994). Gagnon and Bergeron (2017) observed the forces and motion of a mussel long-line system in the open ocean to determine the drag coefficient of the droppers and shielding effect on the bulk drag force exerted by steady currents.

Numerical Method

Numerical models using the finite element method were developed or adapted to predict the loading and motion of raft facilities of various designs under currents and monochromatic wave forcing (Stevens et al. 2008; Tsukrov et al. 2003). A simulation model of the structure involving the lumped mass method was used to calculate the displacement and mooring line forces of an off-shore submerged buoy cable structure subjected to ocean waves (Matsubara et al. 1985). To numerically examine suspended long-line culture systems with lantern nets, López et al. (2017) analyzed the stress on a submersible long-line culture system with lantern nets subjected to parallel and perpendicular forces by using a dynamic simulation model based on the finite element method. Many studies have proposed that suspended kelp and scallop aquaculture systems affect the circulation and considerably reduce current speeds (Lin et al. 2016; Plew et al. 2015). In addition, severe fouling may be accompanied by suspended cultivation systems.

Net Cage Culture Distribution and Output in China

According to the statistics of the China Fishery Statistical Yearbook of 2020, the output of the traditional net cage culture in 2019 was 550,317 tons, 7.44% less than that in 2018, accounting for 2.66% of the total culture output in 2019. Moreover, the traditional cage culture area in 2019 was 22,926,367 m², 55.74% less than that in 2018, accounting for 0.12% of the total culture area in China in 2019 (Table 1).

Traditional Aquaculture Structures, Table 1 Output and area of traditional cage culture in all provinces in 2019

Region	Output (t)	Aquaculture area (m ²)
Total	550,317	22,926,367
Liaoning	1576	373,071
Zhejiang	23,317	619,192
Fujian	283,128	14,682,814
Shandong	71,950	2,179,784
Guangdong	119,662	3,446,924
Guangxi	33,224	612,493
Hainan	17,460	1,012,089

Traditional Aquaculture Structures, Table 2 Output and area of raft culture in all provinces in 2019

Guangxi	370,480	6926

Raft Culture Distribution and Output in China

According to the statistics of the China Fishery Statistical Yearbook of 2020, the raft culture output in 2019 was 6174,565 tons, corresponding to an increase of 0.79% compared to that in 2018, accounting for 29.9% of the total culture production in 2019. The raft aquaculture water area was 325,314 m², corresponding to a decrease of 4.07% compared with that in 2018, accounting for 16.3% of China's total culture area in 2019 (Table 2).

Definition

Ships and other watercraft are used for maritime transport. Types can be distinguished by propulsion, size, or cargo type. Shipping may be for commerce, for recreation, or for military purposes.

Scientific Fundaments

Basic Type and Development History

Most modern transport ships can be placed in one of a few categories.

Bulk carrier, or, bulk freighter, is a merchant ship specially designed to transport unpackaged bulk cargo, such as grains, coal, ore, and cement, in its cargo holds. Since the first specialized bulk carrier was built in 1852, economic forces have fueled the development of these ships, causing them to grow in size and sophistication. Today's bulk carriers are specially designed to maximize capacity, safety, efficiency, and durability. As of 1999, the International Convention for the Safety of Life at Sea defines a bulk carrier as “a ship constructed with a single deck, top side tanks and hopper side tanks in cargo spaces and intended to primarily carry dry cargo in bulk; an ore carrier; or a combination carrier” (van Dokkum 2003) which can be seen in Fig. 1. However, most classification societies use a broader definition where

a bulk carrier is any ship that carries dry unpackaged goods. Multipurpose cargo ships can carry bulk cargo but can also carry other cargoes and are not specifically designed for bulk carriage. The term “dry bulk carrier” is used to distinguish bulk carriers from bulk liquid carriers such as oil, chemical, or liquefied petroleum gas carriers. Very small bulk carriers are almost indistinguishable from general cargo ships, and they are often classified based more on the ship's use than its design (Frankel 1985).

Today, bulk carriers make up 15–17% of the world's merchant fleets and range in size from single-hold mini-bulk carriers to mammoth ore ships able to carry 400,000 metric tons of deadweight (DWT) (Haylar 2003). A number of specialized designs exist: some can unload their own cargo, some depend on port facilities for unloading, and some even package the cargo as it is loaded. Over half of all bulk carriers have Greek, Japanese, or Chinese owners, and more than a quarter are registered in Panama. South Korea is the largest single builder of bulk carriers, and 82% of these ships were built in Asia.

Container ship is the cargo ship that carries entire load in truck-size containers, in a technique called containerization. They form a common means of commercial intermodal freight transport. Informally known as “box boats,” they carry the majority of the world's dry cargo. Most container ships are propelled by diesel engines and have

Transport Ship,

Fig. 1 Bulk carrier – Sabrina I. (<https://en.wikipedia.org/>)

about 10 to 30 crew members. They generally have a large accommodation block at the stern, directly above the engine room. Since the 1960s the transport of containers has continued to grow. The specific advantage of the use of containers is that the cargo can be transported directly from customer to customer, and not just from port to port. The transport by water is just a link in the chain of transport. Container vessels have grown from a capacity of 1500 TEU (1966) to approximately 8000 (2002) (van Dokkum 2003).

The sizes of containers vary. The ISO standards distinguish the TEU and the FEU, which may differ in height.

TEU = 20 ft equivalent unit. The nominal length of these containers is 6.10 m. The actual length is 38 mm shorter, leaving some space between the containers.

FEU = 40 ft equivalent unit. The nominal length of these containers is 12.20 m.

Today, about 90% of non-bulk cargo worldwide is transported by container ships, and the largest modern container ships can carry over 21,000 TEU. Container ships now rival crude oil tankers and bulk carriers as the largest commercial seaborne vessels.

Container ships are distinguished into seven major size categories: small feeder,

feeder, feedermax, Panamax, Post-Panamax, New Panamax, and ultra-large. As of December 2012, there were 161 container ships in the VLCS class (Very Large Container Ships, more than 10,000 TEU), and 51 ports in the world can accommodate them (Cudahy 2006).

The size of a Panamax vessel is limited by the original Panama Canal's lock chambers, which can accommodate ships with a beam of up to 32.31 m, a length overall of up to 294.13 m, and a draft of up to 12.04 m. The Post-Panamax category has historically been used to describe ships with a molded breadth over 32.31 m; however, the Panama Canal expansion project has caused some changes in terminology (Haylar 2003). The New Panamax category is based on the maximum vessel size that is able to transit a new third set of locks, which opened in June 2016; it can be found in Fig. 2. The third set of locks were built to accommodate a container ship with a length overall of 366 m (1,201 ft), a maximum width of 49 m (161 ft), and tropical freshwater draft of 15.2 m (50 ft). Such a vessel, called New Panamax class, is wide enough to carry 19 rows of containers, can have a total capacity of approximately 12,000 TEU, and is comparable in size to a capesize bulk carrier or a Suezmax tanker.

Transport Ship,

Fig. 2 MV Mærsk Mc-Kinney Møller. (<https://en.wikipedia.org/>)

Tankers are cargo ships for the transport of fluids, such as crude oil, petroleum products, liquefied petroleum gas (LPG), liquefied natural gas (LNG), and chemicals, also vegetable oils, wine, and other food – the tanker sector comprises one third of the world tonnage. Major types of tankship include the oil tanker, the chemical tanker, and gas carrier. Tankers also carry commodities such as vegetable oils, molasses, and wine. In the US Navy and Military Sealift Command, a tanker used to refuel other ships is called an oiler (or replenishment oiler if it can also supply dry stores), but many other navies use the terms tanker and replenishment tanker (Wiltshire 2008).

In 1954, Shell Oil developed the average freight rate assessment (AFRA) system, which classifies tankers of different sizes. To make it an independent instrument, Shell consulted the London Tanker Brokers' Panel (LTBP). At first, they divided the groups as General Purpose for tankers under 25,000 tons deadweight (DWT), Medium Range for ships between 25,000 and 45,000 DWT, and Large Range for the then-enormous ships that were larger than 45,000 DWT (Haylar 2003). The very large crude carrier MV Sirius Star is shown in Fig. 3. The ships became larger during the 1970s, and the list was extended, where the tons are long tons:

10,000–24,999 DWT: Small tanker
 25,000–34,999 DWT: Intermediate tanker
 35,000–44,999 DWT: Medium Range 1 (MR1)
 45,000–54,999 DWT: Medium Range 2 (MR2)
 55,000–79,999 DWT: Large Range 1 (LR1)
 80,000–159,999 DWT: Large Range 2 (LR2)
 160,000–319,999 DWT: Very Large Crude Carrier (VLCC)
 320,000–549,999 DWT: Ultra Large Crude Carrier (ULCC)

Refrigerated ships (usually called reefers) are cargo ships typically used to transport perishable commodities which require temperature-controlled transportation, mostly fruits, meat, fish, vegetables, dairy products, and other food-stuffs. The reefer ship Dole Honduras unloading bananas is a kind of typical ship, as can be found in Fig. 4.

Reefer ships may be categorized into three types:

1. Side-door vessels have watertight ports on the ship's hull, which open into a cargo hold. Elevators or ramps leading from the quay serve as loading and discharging access for the forklifts or conveyors. Inside these access ports or side doors, pallet lifts or another series of conveyors bring the cargo to the respective

Transport Ship,

Fig. 3 The very large crude carrier MV Sirius Star. (<https://en.wikipedia.org/>)

Transport Ship,

Fig. 4 The reefer ship Dole Honduras unloading bananas. (<https://en.wikipedia.org/>)

decks. This special design makes the vessels particularly well suited for inclement weather operations as the tops of the cargo holds are always closed against rain and sun.

2. Conventional vessels have a traditional cargo operation with top opening hatches and cranes/derricks. On such ships, when facing wet weather, the hatches need to be closed to prevent heavy rain from flooding the holds. Both above ship types are well suited for the handling of palletized and loose cargo.
3. Refrigerated container ships are specifically designed to carry containerized unit loads where each container has its individual refrigerated unit. These containers are nearly always 20 ft equivalent units (often called TEU) that are the size of “standard” cargo containers that are loaded and unloaded at container terminals and aboard container ships. These ships differ from conventional container ships in their design, power generation, and electrical distribution equipment. They need provisions made for powering each container’s cooling system. Because of their ease of loading and unloading cargo, many container ships are now being built or redesigned to carry refrigerated containers (Kohli 2000).

Roll-on/roll-off (RORO or ro-ro) ships are vessels designed to carry wheeled cargo, such as cars, trucks, semitrailer trucks, trailers, and railroad cars, that are driven on and off the ship on

their own wheels or using a platform vehicle, such as a self-propelled modular transporter (Emi 2006).

Types of RORO vessels include ferries, cruiseferries, cargo ships, barges, and RORO service for air deliveries. New automobiles that are transported by ship are often moved on a large type of RORO called a pure car carrier (PCC) or pure car/truck carrier (PCTC).

Elsewhere in the shipping industry, cargo is normally measured by the metric ton, but RORO cargo is typically measured in lanes in meters (LIMs). This is calculated by multiplying the cargo length in meters by the number of decks and by its width in lanes (lane width differs from vessel to vessel, and there are several industry standards). On PCCs, cargo capacity is often measured in RT or RT43 units (based on a 1966 Toyota Corona, the first mass-produced car to be shipped in specialized car carriers and used as the basis of RORO vessel size. 1 RT is approximately 4 m of lane space required to store a 1.5 m wide Toyota Corona) or in car-equivalent units (CEU). Figure 5 shows a pure car carrier ship’s starboard side.

The largest RORO passenger ferry is MS Color Magic, a 75,100 GT cruise ferry that entered service in September 2007 for Color Line. Built in Finland by Aker Finnyards, it is 223.70 m (733 ft 11 in) long and 35 m (114 ft 10 in) wide and can carry 550 cars or 1270 lane meters of cargo.

Transport Ship, Fig. 5 A pure car carrier ship's starboard side. (<https://en.wikipedia.org/>)

Transport Ship, Fig. 6 The largest car/truck carrier – MV Tønsberg. (<https://en.wikipedia.org/>)

The RORO passenger ferry with the greatest car-carrying capacity is Ulysses, owned by Irish Ferries. Ulysses entered service on 25 March 2001 and operates between Dublin and Holyhead. The 50,938 GT ship is 209.02 m (685 ft 9 in) long

and 31.84 m (104 ft 6 in) wide and can carry 1342 cars/4101 lane meters of cargo (Fig. 6).

The PCTC has liftable decks to increase vertical clearance, as well as heavier decks for “high-and-heavy” cargo. A 6,500-unit car ship,

with 12 decks, can have three decks which can take cargo up to 150 short tons (136 t; 134 long tons) with liftable panels to increase clearance from 1.7 to 6.7 m (5 ft 7 in to 22 ft 0 in) on some decks. Lifting decks to accommodate higher cargo reduces the total capacity.

These kinds of vessels perform a usual speed of 16 knots at eco-speed, while at full speed can achieve more than 19 knots.

With the building of Wallenius Wilhelmsen Logistics's 8,000-CEU car carrier *Faust* out of Stockholm in June 2007, car carriers entered a new era of the large car and truck carrier (LCTC) (Llovio 2007). Currently, the largest are Hoegh Autoliners Six Horizon class vessels with capacity of 8,500 CEU each.

The car carrier *Auriga Leader*, belonging to Nippon Yusen Kaisha, built in 2008 with a capacity of 6,200 cars, is the world's first partially solar-powered ship.

Ocean liner is the passenger ship primarily used as a form of transportation across seas or oceans. Liners may also carry cargo or mail and may sometimes be used for other purposes (e.g., for pleasure cruises or as hospital ships).

Ocean liners are usually strongly built with a high freeboard to withstand rough seas and adverse conditions encountered in the open ocean. Additionally, they are often designed

with thicker hull plating than is found on cruise ships and have large capacities for fuel, food, and other consumables on long voyages.

The first ocean liners were built in the mid-nineteenth century. Technological innovations such as the steam engine and steel hull allowed larger and faster liners to be built, giving rise to a competition between world powers of the time, especially between the United Kingdom and Germany. Once the dominant form of travel between continents, ocean liners were rendered largely obsolete by the emergence of long-distance aircraft after World War II. Advances in automobile and railway technology also played a role. By 2015, RMS *Queen Mary 2* is the only ship still in service as an ocean liner, the RMS *Queen Elizabeth 2* having retired a few years prior; it can be seen in Fig. 7.

Ferries are a form of transport, usually a boat or ship, but also other forms, carrying (or ferrying) passengers and sometimes their vehicles. Ferries are also used to transport freight (in lorries and sometimes unpowered freight containers) and even railroad cars. Most ferries operate on regular, frequent, return services. A foot-passenger ferry with many stops, such as in Venice, is sometimes called a water-bus or water taxi. Ferries form a part of the public transport systems of many

Transport Ship, Fig. 7 Queen Mary 2–05. (<https://en.wikipedia.org/>)

Transport Ship,

Fig. 8 The Staten Island Ferry – commuters between Manhattan and Staten Island in NYC.

(<https://en.wikipedia.org/>)

waterside cities and islands, allowing direct transit between points at a capital cost much lower than bridges or tunnels.

Ferry boats often dock at specialized facilities designed to position the boat for loading and unloading, called a ferry slip. If the ferry transports road vehicles or railway carriages, there will usually be an adjustable ramp called an apron that is part of the slip. In other cases, the apron ramp will be a part of the ferry itself, acting as a wave guard when elevated and lowered to meet a fixed ramp at the terminus – a road segment that extends partially underwater.

Some of world's busiest ferry routes include the Star Ferry in Hong Kong and the Staten Island Ferry in New York City. The Staten Island Ferry is shown in Fig. 8.

Design Consideration

Bulk carriers are usually discharged by grabs or by suction pipes. Pouring the cargo through a shooter or via a conveyor belt doses the loading. Bulk carriers have large upper and lower ballast tanks to give the empty vessel enough draft and a better behavior while in transit (van Dokkum 2003). Ship transporting ore have a special design. Ore is very heavy (stowage factor is approximately $0.5 \text{ m}^3/\text{t}$), and thus ships only need small holds to be loaded completely. To prevent a too large stability, the holds must not be situated too low or too

close to the sides of the ships. Some bulk carriers can also function as a tanker.

Tankers are a relatively new concept, dating from the later years of the nineteenth century. Before this, technology had simply not supported the idea of carrying bulk liquids. The market was also not geared toward transporting or selling cargo in bulk; therefore, most ships carried a wide range of different products in different holds and traded outside fixed routes. Liquids were usually loaded in casks – hence the term “tonnage” refers to the volume of the holds in terms of how many tuns or casks of wine could be carried. Even potable water, vital for the survival of the crew, was stowed in casks. Carrying bulk liquids in earlier ships posed several problems:

1. Loading and discharging: Bulk liquids must be pumped – The development of efficient pumps and piping systems was vital to the development of the tanker. Steam engines were developed as prime movers for early pumping systems. Dedicated cargo handling facilities were now required ashore too – As was a market for receiving a product in that quantity. Casks could be unloaded using ordinary cranes, and the awkward nature of the casks meant that the volume of liquid was always relatively small – Therefore keeping the market more stable.

2. Free surface effect: A large body of liquid carried aboard a ship will impact on the ship's stability, particularly when the liquid is flowing around the hold or tank in response to the ship's movements. The effect was negligible in casks but could cause capsizing if the tank extended the width of the ship, a problem solved by extensive subdivision of the tanks.

Key Applications

Maritime transport can be realized over any distance by boat, ship, sailboat, or barge, over oceans and lakes, through canals, or along rivers. While extensive inland shipping is less critical today, the major waterways of the world including many canals are still very important and are integral parts of worldwide economies. Virtually any material can be moved by water; however, water transport becomes impractical when material delivery is time-critical such as various types of perishable produce. However, water transport is highly cost-effective with regular schedulable cargoes, such as transoceanic shipping of consumer products – and especially for heavy loads or bulk cargos, such as coal, coke, ores, or grains. Arguably, the industrial revolution took place best where cheap water transport by canal, navigations, or shipping by all types of watercraft on natural waterways supported cost-effective bulk transport.

Recreational or educational craft still use wind power, while some smaller craft use internal combustion engines to drive one or more propellers or, in the case of jet boats, an inboard water jet. In shallow draft areas, such as the Everglades, some craft, such as the hovercraft, are propelled by large pusher-prop fans.

Definition

The TAO buoys are the buoys especially designed for studying the macro phenomenon called El Niño, and it was motivated by the 1982–1983 El Niño events. The Tropical Atmosphere Ocean (TAO) project is a major international effort that instrumented the entire tropical Pacific Ocean with approximately 70 deep ocean moorings/buoys. The development of the TAO array started in 1985 and led by the TAO Project Office of the Pacific Marine Environmental Laboratory (PMEL), the full array of 70 moorings was completed in 1994 (see Fig. 1) (tao.ndbc.noaa.gov/proj_overview/proj_overview_ndbc 2018). The TAO array was renamed as the TAO/TRITON array on 1 January 2000.

The array is a major component of the El Niño/Southern Oscillation (ENSO) Observing System, the Global Climate Observing System (GCOS), and the Global Ocean Observing System (GOOS).

Scientific Fundamentals

The TAO array consists of several types of moorings among which the Next Generation ATLAS (Autonomous Temperature Line Acquisition System) moorings are the dominant ones at present. Prior to the Next Generation ATLAS moorings, the standard ATLAS moorings were used as the

Tropical Atmosphere Ocean (TAO) Buoy, Fig. 1 TAO/TRITON array (tao.ndbc.noaa.gov/proj_overview/proj_overview_ndbc 2018)

dominant ones for the array. A notable improvement to the Next Generation ATLAS moorings were the inductively coupled sensors for subsurface data which simplified fabrication, and therefore, eliminated the thermistor cable and its labor-intensive assembly and deployment procedures (Milburn et al. 1996).

In addition to the ATLAS moorings, other moorings such as T-FLEX moorings, TAO Refresh moorings, Acoustic Doppler Current Profiler moorings, TRITON moorings, and BAILONG moorings are also used in TAO array. In this section, various TAO/TRITON Mooring types will be introduced.

Historical Standard ATLAS Moorings

After testing and deployment of prototype ATLAS moorings, the first elements of the large-scale monitoring TAO array were deployed in the eastern Pacific in November 1984. The full TAO array was eventually completed in December 1994. The standard ATLAS mooring (shown in Fig. 2) had a design lifetime of one year, and the system proved to be robust and reliable. Over 500 Standard ATLAS moorings were deployed between 1984 and 2001. The final standard ATLAS was recovered in November 2001 and Next Generation ATLAS moorings are now used exclusively in the TAO array.

Tropical Atmosphere Ocean (TAO) Buoy,
Fig. 2 Standard ATLAS mooring (pmel.noaa.gov/gtmb 2018)

Standard ATLAS moorings measured surface winds, air temperature, relative humidity, sea surface temperature, and ten subsurface temperatures from a 500 m long thermistor cable. Daily-mean data were telemetered to shore in near real-time via NOAA's polar-orbiting satellites and Service Argos. A small subset of hourly values (2–3 per day) coinciding with satellite passes were also transmitted in real time. Hourly values of surface data were internally recorded and available after mooring recovery (pmel.noaa.gov/gtmb 2018).

The Standard ATLAS buoy is a 2.3 m diameter toroid fabricated with fiberglass over a foam core with a simple aluminum tower and a rigid stainless-steel bridle. Nonrotating 0.96 cm diameter 3×19 wire rope is used in the upper 500 m of the mooring. Eight-strand plaited nylon line is used for the compliant member of the mooring with an acoustic release above a 2000 kg railroad wheel anchor and a typical mooring scope of 0.98. An electrical cable with breakouts is clamped parallel to the wire rope for telemetering data from subsurface sensors to the buoy. Active sensors transmit data in a simple time-multiplexed scheme using frequency encoding on a common data/power line. Electronics and batteries are housed in an aluminum tube on the tower of the buoy with meteorological sensors, sea surface temperature, and the subsurface cable connected to the tube through a cast aluminum top cap with marine penetrators. This “low-tech” approach has kept the cost of an individual system down, enabling the array to be completed and maintained on a relatively small budget (tao.ndbc.noaa.gov/proj_overview/pubs/mil96paper 2018).

The sensor systems and sampling schemes on the Standard ATLAS system have been standardized as described in Mangum et al. (1995).

The system measures vector-averaged winds, air temperature, relative humidity, sea surface temperature (SST), 10 subsurface temperatures to a depth of 500 m, and pressure of the lower two temperature sensors. The moorings are designed to be recovered and redeployed after a nominal 1-year period. Data is transmitted daily via Service Argos in three 32-byte buffers and is available to the community in near real time via

the GTS, the World Wide Web, and anonymous FTP.

Next Generation ATLAS Moorings

The first Next Generation systems were deployed in the array in May 1996. The transition to Next Generation systems throughout the array was completed in November 2001. Compared to the Standard ATLAS moorings, the Next Generation ATLAS moorings have the following advantages (tao.ndbc.noaa.gov/proj_overview/pubs/mil96paper 2018):

- Improved data quality
- Added new sensors
- Increased temporal resolution of internally recorded data
- Improved reliability to extend system life
- Simplified fabrication procedures
- Reduced costs

The Next Generation ATLAS system shown in Fig. 3 uses the same basic hardware system as described above, but incorporates new electronics, added sensors, and can be deployed with a slack mooring without an acoustic release. Taut moorings maintain the sensor locations on the wire rope at or near the desired depths, but a slack mooring will cause large vertical excursions of the lower sensors. Accurate pressure measurements in the lower modules will be used to map the positions of the temperature measurements using a simple cable model. The longer scope in the moorings will lower the tension in the line and ease the requirements for accurate depth and line-length determinations necessary for taut moorings. Also, the lower part of the moorings will be left in place when the wire rope and sensors are recovered and replaced on service visits, saving the expense of anchors, hardware, and acoustic releases.

The most obvious and significant improvement in the ATLAS system is the incorporation of inductively coupled sensors for subsurface data. The sensors merely clamp onto the wire rope strength member that serves as one of the inductive elements. This simplifies fabrication, since it will no longer be necessary to manufacture the

Tropical Atmosphere Ocean (TAO) Buoy,

Fig. 3 Next Generation ATLAS mooring (pmel.noaa.gov/gtmmba 2018)

sensor cable with its labor-intensive assembly and deployment procedures. Addressable modules on the cable allow the system to be expanded for new sensors by adding the appropriate hardware and software interfaces.

TRITON Moorings

In October 1999, responsibility for TAO moorings along and to the west of 156E was assumed by the Japan Agency for Marine-Earth Science and Technology (JAMSTEC) which has deployed Triangle Trans-Ocean Buoy Network (TRITON) buoys at those locations. Data from both ATLAS and TRITON moorings are merged in a common data base and available from both PMEL and

JAMSTEC. M-TRITON moorings, a smaller TRITON mooring also developed by JAMSTEC are deployed in RAMA mooring (pmel.noaa.gov/gtmmba 2018).

The TRITON moorings consist of 12 conductivity and temperature sensors that are installed at depths of 1.5 m, 25 m, 50 m, 75 m, 100 m, 125 m, 150 m, 200 m, 250 m, 300 m, 500 m, and 750 m (Ando et al. 2005). A single current meter is at 10 m, and surface meteorological sensors are mounted on the tower of the mooring. Other sensors on TRITON moorings measure temperature, salinity, wind speed and direction, air temperature and relative humidity, short-wave radiation, and rainfall. Figure 4 shows the TRITON Buoy mooring configuration.

Tropical Atmosphere Ocean (TAO) Buoy,
Fig. 4 TRITON Buoy
 (jamstec.go.jp 2018)

T-FLEX Moorings

“Tropical Flex (T-FLEX)” moorings were developed by the Engineering Division at PMEL to replace the Next Generation ATLAS moorings in RAMA and PIRATA as components become obsolete mooring (pmel.noaa.gov/gtmba 2018). T-Flex moorings allow greater flexibility with respect to number and types of instruments that may be deployed, and utilize more commercial off-the-shelf instrumentation.

T-Flex electronics are housed in drop-in canisters for deployment in a modified ATLAS toroid (filled toroid with 2 wells for canisters; 1 for electronics, the second for an external battery). An iridium modem and antenna are integrated into the T-flex canister. There is also an RF modem on the buoy to enable ship to buoy communications. T-Flex tower modifications include a T-cup handle, cable runs around the lower bars, and an additional mounting pad on top for optional

sensors. Eight (8) T-Flex moorings were deployed alongside ATLAS moorings in RAMA and PIRATA between March 2011 and December 2015. A NOAA Technical Memorandum comparing the system performance and data equivalency is in preparation. The first stand-alone T-Flex was deployed in August, 2015 at 4S 81E.

Hourly values of all measurements are returned to shore via Iridium satellite, formatted into WMO BUFR code, and placed on the GTS by PMEL. Higher resolution data are logged internally, and downloaded once the mooring is recovered.

TAO Refresh Moorings

The TAO Array has transitioned from the National Oceanic and Atmospheric Administration's (NOAA) research arm (Pacific Marine Environmental Laboratory, PMEL) to its operational arm within the National Weather Service at the National Data Buoy Center (NDBC). NDBC's transition strategy had two motives: First, to maintain continuity of the existing observations for the climate record and, second (but equally as important) to ensure its future contributions and survival which will be accomplished by a comprehensive equipment upgrade, known as the TAO Technology Refresh (TAO Refresh). TAO Refresh was always an important component of NDBC's transition of the Array. Presently, the Array uses the Next Generation ATLAS mooring system, designed in the 1990s and the deployments completed in 2001, now termed TAO Legacy (tao.ndbc.noaa.gov/proj_overview/mooring_ndbc 2018).

As part of a comprehensive test plan to ensure continuity of the climate records, NDBC conducted laboratory tests and several prototype TAO Refresh systems deployed in the Gulf of Mexico and the Pacific TAO array. Currently eight (8) TAO Refreshed buoys are deployed in the Pacific for in-situ testing with TAO Legacy. The intention is to reduce to 5 TAO Refreshed buoys for extended testing. Initial evaluations indicate good agreement between TAO Legacy and TAO Refresh. These refresh buoys are deployed adjacent to legacy buoys, which are considered a co-located buoy. The refresh buoy data will be available via the Global Telecommunication System (GTS) under the SXPA01

KWNB header in World Meteorological Organization (WMO) FM-18 BUOY alphanumeric formats. The Refreshed buoy is designed to meet requirements for National Weather Service, climate research, and international Global Ocean Observing System (GOOS) and Global Climate Observing System (GCOS) purposes while increasing the real-time data available for climate analysis, forecasts, and numerical model predictions.

Acoustic Doppler Current Profiler Moorings

Subsurface Acoustic Doppler Current Profiler (ADCP) moorings are deployed at a few locations to provide velocity profiles the upper 200–300 m of the water column. ADCP moorings are mostly deployed at equatorial locations where geostrophy breaks down and direct velocity measurements are required. ADCPs are usually deployed in tandem with nearby surface moorings, which may also measure velocity as a backup to the ADCP and/or to provide velocity data near the surface where acoustic back scatter from the sea surface interferes with the ADCP signal. The vertical resolution of the ADCP is about 8 m. ADCP data are available only after the subsurface moorings are recovered mooring (pmel.noaa.gov/gtmmba 2018).

BaiLong Moorings

China's First Institute of Oceanography (FIO) has introduced ATLAS-like moorings, known as BaiLong, one of which occupies a RAMA site. Data from this mooring is telemetered to and quality controlled by FIO and made available on the GTMBA data web page.

With the above moorings, now NDBC provides the measured data and analysis on daily basis from the TAO buoys. Figure 5 shows the plots of the sea surface temperature and wind measurements from the TAO/TRITON buoys mooring (pmel.noaa.gov/gtmmba 2018).

Key Applications

The TAO/TRITON array was extended to the Global Tropical Moored Buoy Array (GTMBA,

Tropical Atmosphere Ocean (TAO) Buoy, Fig. 5 Sea surface temperature and wind measurements (tao.ndbc.noaa.gov/refreshed/index 2018)

Tropical Atmosphere Ocean (TAO) Buoy, Fig. 6 Full View of the Global Tropical Moored Buoy Array (tao.ndbc.noaa.gov/refreshed/index 2018)

see Fig. 6) after mid-1990, with the additions of the Prediction and Research Moored Array in the Tropical Atlantic (PIRATA), and the Research Moored Array for African-Asian-Australian Monsoon Analysis and Prediction (RAMA) in the Indian Ocean. Now the GTMBA is a global system with its interest spanning intraseasonal-to-decadal and longer timescales on global basis, including:

- El Niño/Southern Oscillation and its decadal modulation in the Pacific
- The meridional gradient mode and equatorial warm events in the Atlantic

- The Indian Ocean Dipole
- The mean seasonal cycle, including the Asian, African, Australian, and American monsoons
- The intraseasonal Madden-Julian Oscillation, which originates in the Indian Ocean but affects all three ocean basins
- Trends that may be related to global warming

The Prediction and Research Moored Array in the Tropical Atlantic (PIRATA) was designed to study ocean-atmosphere interactions in the tropical Atlantic that affect regional weather and climate variability on seasonal, interannual, and longer time scales. Ocean-atmosphere

interactions in this region influence the development of droughts, floods, severe tropical storms, and hurricanes, with impacts felt by millions of people in the Americas and Africa. PIRATA was first established in the mid-1990s and has undergone expansions and enhancements since 2005 to improve its utility for ocean and climate research and forecasting. PIRATA is supported by France (IRD, Météo-France, CNRS and IFREMER), Brazil (INPE and DHN), and the USA (NOAA).

The Research Moored Array for African-Asian-Australian Monsoon Analysis and Prediction (RAMA) was designed to study the Indian Ocean's role in the monsoons. One third of the world population depends on monsoon driven rainfall for agricultural production, so improving our understanding and ability to predict the monsoons has been a long-standing objective of the international scientific community. RAMA, the newest tropical buoy array, was initiated in the traditionally data sparse Indian Ocean in 2004 following deployment of successful pilot scale arrays by Japan and India. RAMA has since grown through the formation of new partnerships that at present include Indonesia, China, the USA, and the Bay of Bengal Large Marine Ecosystem (BOBLME) program.

Tsunami Warning Buoy

Mingfang Li
 Wuhan University of Science and Technology,
 Wuhan, China

Definition

Tsunami Warning Buoy is a floating device designed as part of the Tsunami Warning System. Paired with a sensor on the ocean floor that watches for seismic activity, the buoy is a communications hub that transmits tsunami data to an international network and helps give affected populations a few precious minutes to prepare.

Synonyms

[DART: Deep-Ocean Assessment and Reporting of Tsunamis](#); [TDB: Tsunami Detection Buoy](#); [TWS Tsunami Warning System](#)

Scientific Fundamentals

Introduction

Tsunamis are huge waves of water caused by displacement during the natural disaster such as earthquakes, landslides, volcano eruptions, or meteorite impacts, and their force can cause massive damage, about 86% of tsunamis are caused

by earthquakes. Tsunamis travel at very fast speeds, and they often exceed 160 km per hour and can reach up to 800 km per hour (in the deep ocean). As the waves approach the coast, their speed decreases and their amplitude increases. A tsunami that is just a meter in height in the deep ocean can grow to tens of meters waves at the shoreline, which can devastate the coastlines of entire ocean basins, as happened with the 2004 tsunami which affected areas from Somalia to Indonesia. About 99% of tsunami fatalities occur within 250 km of the tsunami's origin.

From an initial tsunami generating source area, waves travel outward in all directions much like the ripples caused by throwing a rock into a pond. As these waves approach coastal areas, the time between successive wave crests varies from 5 to 90 min. The first wave is usually not the largest in the series of waves, nor is it the most significant. Furthermore, one coastal community may experience no damaging waves while another, not that far away, may experience destructive deadly waves. Depending on several factors, some low-lying areas could experience severe inland inundation of water and debris of more than 300 meters.

The first early tsunami warning systems developed in Hawaii, but it was not until the late twentieth century that today's tsunami warning system was developed and launched off the northwest coast of the USA. The National Oceanic and Atmospheric Administration (NOAA) Tsunami Warning Centre (website see (The National Oceanic 2018)) is a scientific agency that tries to limit the damage that tsunamis can do by strategically placing buoys along the areas where there is a history of tsunamis. These booths provide early warnings of possible tsunamis. Buoys such as DART (Deep-ocean Assessment Reading Tsunamis) were originally developed by NOAA to detect tsunamis. These stations are placed in regions with a history of destructive tsunamis.

NOAA operates these tsunami warning centers, namely National Tsunami Warning Center (NTWC, website see (National Tsunami Warning Center 2018)), NTWC responsible for coastal waters from Alaska to California, including Washington), Pacific Tsunami Warning Center

(PTWC, website see (Pacific Tsunami Warning Center 2018)), PTWC responsible for all American interests in the Pacific, including Hawaii), and International Tsunami Warning Center (ITWC, website see (International Tsunami Warning Center 2018)), ITWC responsible for the other 25 member nations in the Pacific Ocean Basin).

International Tsunami Information Center (ITIC) has published a 12-page brochure, *Tsunami The Great Waves* (Tsunami 2018), which provides information on what tsunamis are, how fast and how big they can be, and what causes them, and describes programs undertaken to mitigate this hazard, including the development of tsunami warning centers, research programs, and safety rules describing what to do when a tsunami attacks your coastline. The English version was last updated and revised in December, 2014. It is also available in Spanish, French, and Chinese.

Scientific Fundamentals of Tsunami Warning Buoy

Usually the tsunami buoys are located near some trench or borders between plates, where most of tsunami events in the world were generated. The determination of location follows some important rules. One of the most is that the tsunami buoys can record real time typical tsunami wave in no more than half an hour after earthquake-generated tsunami occurred. There are two main functions for tsunami detection buoy, one is to detect whether the tsunami is generated and record typical tsunami wave in 15–30 min and show after earthquake occurred; the other is that the real-time tsunami wave data can be assimilated into forecasting system to improve the accuracy in tsunami forecasts.

A tsunami warning buoy has two components: the surface buoy and the underwater sensor (see Fig. 1). The underwater sensor has two modes, the standard mode and the event mode. The underwater sensor is usually at standard mode most of the time. When on-board software identifies a possible tsunami, the station leaves standard mode and begins transmitting in event mode. Here, we will take the commercial product DART II (Deep-ocean Assessment and Reporting of Tsunamis) systems to explain the scientific fundamental of

Tsunami Warning Buoy, Fig. 1 DART system configuration: a diagram of the Dart II system. (Figure from Deep-ocean Assessment and Reporting of Tsunamis (DART) 2018)

the tsunami warning system; more details about the systems can be found in website (Deep-ocean Assessment and Reporting of Tsunamis (DART) 2018).

The systems (as shown in Fig. 1) consist of an anchored seafloor bottom pressure recorder (BPR) and a companion-moored surface buoy for real-time communications (Gonzalez et al. 1998). An

acoustic link transmits data from the BPR on the seafloor to the surface buoy.

The BPR collects temperature and pressure at 15-s intervals. The pressure values are corrected for temperature effects and the pressure converted to an estimated sea-surface height (height of the ocean surface above the seafloor) by using a constant 670 mm/psia. The system has two data reporting modes, standard and event. The system operates routinely in standard mode, in which four-spot values (of the 15-s data) at 15-min intervals of the estimated sea surface height are reported at scheduled transmission times. When the internal detection software (Deep-ocean Assessment and Reporting of Tsunamis (DART) Tsunami 2018) identifies an event, the system ceases standard mode reporting and begins event mode transmissions. In event mode, 15-s values are transmitted during the initial few minutes, followed by 1-min averages. Event mode messages also contain the time of the initial occurrence of the event. The system returns to standard transmission after 4 h of 1-min real-time transmissions if no further events are detected. The link (Deep-ocean Assessment and Reporting of Tsunamis (DART II) 2018) shows an animation for us to understand how the system works.

Tsunami Detection Algorithm

Tsunamis differ from wind-generated waves in that they are characterized as a shallow-water wave even in the deep ocean, and their pressure

wave extends all the way to the sea floor, whereas standard surface wave pressures can only be measured at about half their wavelength below the surface. The deep-ocean provides the perfect filter for detecting Tsunamis, eliminating all the noise from the surface waves. As a result, the BPR registers only the tidal fluctuations and tsunamis. The BPR is extremely sensitive and can detect water level changes of one millimeter or less, which is critical since tsunamis in deep water may only be a centimeter tall. Figure 2 shows the data acquired from NOAA buoy 46,407 off the coast of Oregon; as we can see, it follows the tidal cycle. Figure 3 shows a tsunami detected by NOAA buoy 32,412 on 27th February 2010 off the coast of Chile; at time “1,” the buoy went into event mode due to a magnitude 8.8 earthquake in Chile; 3 h later at time “2,” a tsunami was measured at the buoy site with a height of 24 cm. The pressure data is transmitted through the water column using an acoustic model and is then relayed off the buoy through the Iridium satellite network to the warning center. There that data is fed into models to improve the predictions and forecasting for the size and areas of impact of the tsunami.

The tsunami detection algorithm must exclude the effects of white noise and tidal. As a result of this, the algorithm set a threshold value for the estimated amplitude of the pressure fluctuations within the tsunami frequency band, i.e., 30 mm in the North Pacific Ocean, which is based on the

Tsunami Warning Buoy,

Fig. 2 The pressure data of buoy 46,407 off the coast of Oregon. We can view all of NOAA’s oceanographic data buoys and their associated data on the National Data Buoy Center (NDBC) Website (National Data Buoy Center (NDBC) 2018)

Tsunami Warning Buoy,

 by buoy 32,412 on 27th
 February 2010 off the
 coast of Chile

observation of the background oceanic noise in the past years. The predictions will update every 15 s (i.e., DART II). Once the estimated amplitudes exceed the threshold, the gauge goes into a rapid reporting mode to provide detailed information about the tsunami. It will remain in this mode for at least 4 h.

Figure 4 shows the application of the algorithm to a theoretical pressure series in DART (Deep-ocean Assessment and Reporting of Tsunamis (DART) Tsunami 2018). The series consists of an M2 tide with an amplitude of 1 meter and a short pulse that has an amplitude of 5 cm and a duration of 15 min. The pulse affects the difference both directly and through its indirect effect on the prediction. Following the first and largest differences, pulses continue to occur each hour with diminishing amplitude until the pulse no longer influences the predictions. As shown in Fig. 4, a software flag is set to -1 each time the difference exceeds the threshold. In turn, this exceedance flag controls a reporting flag that puts the DART gauge into its rapid reporting mode. The reporting flag is set to -1 as soon as the threshold is exceeded and remains equal to -1 until 4 h has passed since the last time the threshold was exceeded. The gauge then returns to its monitoring mode.

Figure 5 shows small-amplitude tsunamis observed by internally recording gauges in the North Pacific (Deep-ocean Assessment and Reporting of Tsunamis (DART) Tsunami 2018).

Relative to the high-passed data, the background noise in the difference series is either equal in amplitude or slightly enhanced. Neither tsunami is high enough in amplitude to set a DART gauge into rapid reporting mode.

Applications

Dart II

The first-generation DART I systems had one-way communications from the BPR to the Tsunami Warning Centers (TWC) and National Data Buoy Center (NDBC) via the western Geostationary Operational Environmental Satellite (GOES West) (Milburn et al. 1996). DART I became operational in 2003. NDBC replaced all DART I systems with the second-generation DART II systems in early 2008. DART I transmits standard mode data once an hour (four estimated sea-level height observations at 15-min intervals). For information about the development history of this technology, see (NOAA Center for Tsunami Research 2018).

DART II became operational in 2005 (Green 2006). A significant capability of DART II is the two-way communications between the BPR and the TWCs/NDBC using the Iridium commercial satellite communications system (Meinig et al. 2005). The two-way communications allow the TWCs to set stations in event mode in anticipation

of possible tsunamis or retrieve the high-resolution (15-s intervals) data in 1-h blocks for detailed analysis. DART II systems transmit standard mode data, containing 24 estimated sea-level height observations at 15-min intervals, once every 6 h. The two-way communications allow for real-time troubleshooting and diagnostics of the systems. These buoys have two independent and redundant communications systems. NDBC distributes the data from both transmitters under separate transmitter identifiers. NDBC receives the data from the DART II systems, formats the data into bulletins grouped by ocean basin (see

(The NDBC 2018), for a listing of the bulletin headers used for each transmitted identifier), and then delivers them to the National Weather Service Telecommunications Gateway (NWSTG) that then distributes the data in real-time to the TWCs via NWS communications and nationally and internationally via the Global Telecommunications System.

Table 1 gives the performance characteristics and specifications of DART II in summary (Summary of DART II 2018). The DART II Tsunami warning buoys are placed all over the world to protect citizens of countries from dying or

getting injured; Fig. 6 shows the current deployed DART II location (The current deployed DART II 2018).

SAIC Tsunami Buoy

The SAIC Tsunami Buoy (STB) is an enhanced version of commercial tsunami buoy system based on the NOAA DART system in technology. SAIC (Science Applications International Corporation) has patent license agreement from NOAA and remains the only company currently licensed by NOAA to build commercial DART-based tsunami buoys (SAIC 2018). Under the license agreement, SAIC has produced more than 35 s-generation buoy systems based on the NOAA DART II system, and two types of third-

generation systems based on the Easy-to-Deploy (ETD) DART technology. As SAIC enters another decade of work with NOAA, the company is manufacturing more than 85% of the world's commercially deployed tsunami buoys, helping to make the concept of a globally interconnected tsunami buoy network a reality.

In 2006, the SAIC Tsunami Buoy (STB) was born, and the company began manufacturing its first commercial prototype tsunami assessment system. Like the DART II system, the STB has three subsystems: a bottom pressure recorder (BPR), a surface communications buoy, and a mooring subsystem. The third-generation (3G) commercial ETD DART systems are smaller in size and weight compared to the STB but still

Tsunami Warning Buoy, Table 1 Summary of DART II performance characteristics and specifications

Mandatory characteristic	Specification
Measurement sensitivity	Less than 1 millimeter in 6000 meters; 2×10^{-7}
Sampling interval, internal record	15 s
Sampling interval, event reports	15 and 60 s
Sampling interval, tidal reports	15 min
Two-way end-to-end communications	On demand, tsunami warning center (TWC) trigger
Tsunami data report trigger	Automatically by tsunami detection algorithm
Data flow, BPR to TWC	Less than 3 min after triggered event
Desired characteristic	Specification
Reliability and data return ratio	Greater than 80%
Maximum deployment depth	6000 meters
Minimum deployment duration	1 year
Operating conditions	Beaufort 9
Theoretical battery life, buoy	Greater than 2 years
Theoretical battery life, tsunameter	Greater than 4 years
Maximum status report interval	Less than 6 h

Tsunami Warning Buoy, Fig. 6 The current deployed DART II location shown on a map (The current deployed DART II 2018)

maintain DART performance standards. Despite its small size, the ETD DART's performance has been exceptional in challenging locations. SAIC's second- and third-generation buoy systems are currently operational in maritime countries worldwide, including Australia, Chile, China, India, Japan, Russia, and Thailand, and are gathering actionable data for their users and NOAA.

After producing the third generation ETD DART, SAIC developed the hybrid third-generation STB-MF tsunami buoy system

(as shown in Fig. 7). These upgrades included (SAIC 2018):

- Replacement of the standard low-frequency (LF) BPR with a single pressure vessel MF BPR.
- Increased reliability of the BPR by eliminating wet-mate cables and connectors, and reducing from five (5) pressure vessels to one (1).
- Utilization of the updated ETD DART core circuit board package.

Tsunami Warning Buoy, Fig. 7 The hybrid third-generation STB-MF system with single pressure vessel bottom pressure recorder (BPR). (Figure from SAIC 2018)

- Replacement of the bulky, older technology LF transducers with more compact and updated MF transducers, to provide a 60–70° communication cone as opposed to the 40° cone in the LF system.
- More flexible buoy and BPR depth placement due to larger communication cone and watch circle.
- Increased use of inverse catenary moorings that are more robust in higher ocean currents.

Tsunami Warning Buoy,

Fig. 8 The DART 4G system consists of a surface buoy tethered to an anchored seafloor bottom pressure recorder (BPR). (Figure from DART 4G 2018)

To solve the ultimate challenge of near-field tsunamis warning, NOAA Pacific Marine Environmental Laboratory (NOAA PMEL) has developed a fourth-generation (4G) DART system (see Fig. 8), and the developmental 4G DART systems are currently being evaluated off the Chilean and Oregon coasts with good results. The 4G DART includes a new and improved pressure sensor, increased sampling rate, advanced internal processing software, and upgraded power management. A commercial 4G system is expected to be available within the next 12 months (reported in Sep.2016, see (SAIC 2018)).

A New Tsunami Warning Buoy in Japan

Kato et al. (2005) reported a new tsunami warning system, which uses real-time kinematic (RTK) GPS technology to position a GPS receiver mounted on top of a buoy floating at the sea surface, relative to a land-based GPS receiver.

The data are transmitted from buoy to shore using radio transmission. The GPS phase data are processed on a PC placed at the land-based station (see Figs. 9 and 10). The newly designed system is considered a more practical application to tsunami disaster mitigation than to survive for harsher oceanic environments far offshore.

A tsunami due to the 2004 M7.4 September fifth earthquake off the Kii peninsula, Japan, was recorded at the newly designed GPS buoy, about 13 km off the Muroto Promontory, southwestern Japan. The tsunami arrived at the buoy about 8 min before its arrival to the nearest tide gauge station at the tip of the Muroto Promontory. The predicted tsunami record based on preliminary source model shows excellent agreement (rms 2.7 cm) with the observed GPS record. This demonstrates that GPS buoy observations can be used not only for a tsunami warning system, but also for precise determination of the tsunami source.

Tsunami Warning Buoy,

Fig. 9 The monitoring system of the new GPS tsunami warning buoy. (Figure from Kato et al. 2005)

The German-Indonesian Tsunami Early Warning System

Due to the specific geological situation in Indonesia, the previously used, established tsunami warning systems are not optimal for Indonesia. The earthquakes in the Indian Ocean at Indonesia originate along the Sunda Trench, a subduction zone which extends in an arch from the northwest tip of Sumatra to Flores in eastern Indonesia. If a tsunami originates here, in an extreme case, the waves reach the coast within 20 min, so that only very little time remains for an early warning. Therefore, the concept of the German-Indonesian Tsunami Early Warning System (GITEWS) was based on this prevailing condition; the concept is shown in Fig. 11. The buoy that was once used and is now no longer in operation is shown in the Fig. 12.

The GITEWS is primarily based on model-based coupling of seismological data with GPS measurements and level measurements. There are more than 300 sensors distributed across all of Indonesia which supply their data to the warning center in real time. From these dates, a newly developed automatic decision support system (DSS) will compile a picture of the disaster situation, based on which the decision will be made whether to issue an alarm. The following steps will be taken in the process (GITEWS 2018):

- Quake location and strength: Ascertainment with seismological data; all earthquakes (worldwide) are recorded. All earthquakes $M \geq 2$ are evaluated in the national warning center. Earthquake information is basically provided. Tsunami warning alerts are only issued if a tsunami is expected (earthquake magnitude > 7).
- Fracture mechanism: Only strong suboceanic earthquakes with a distinct vertical component can cause tsunamis. An initial assessment as to whether the ocean floor has moved vertically can be determined using land fixed points.
- Ascertainment of a tsunami: On the coasts and on the offshore islands of Indonesia, tide gauges were installed with GPS components, which monitor the sea level. The data are integrated into the warning process.
- Decision-making: Within less than 5 min, the decision can be made as to whether a warning needs to be issued and – if so – to which coastal sections.

In the GITEWS, buoys are measurement instruments for the detection and verification of a tsunami in the early developing stage. The most important information, namely, the fast earthquake location and magnitude, without which either a simulation or a warning can be generated, cannot be supplied by buoy systems. Buoy

Tsunami Warning Buoy,
Fig. 10 A new GPS design
of tsunami warning buoy.
(Figure from Kato et al.
2005)

systems for the direct measurement of a tsunami were initially part of the GITEWS concept. The further development of the GPS Shield made it possible to discontinue pursuing the buoy concept. Therefore, buoys have no longer been part of the operational warning system since 2010, so that the high maintenance cost of buoy installations near coastlines can also be omitted (GITEWS 2018).

After that, GITEWS has developed model calculation methods to determine the possible extent

of a tsunami across the ocean. The measurement data, such as seismological parameters, GPS measurements of land displacements, and coastal tide gauge measurements of the sea level are being included in the model calculations. This results in a dynamic-updated model that constantly reflects the processes in the ocean and can forecast their future progress. The Tsunami Service Bus (TSB) – the integration platform in GITEWS – realizes the service-oriented architecture (SOA) approach by implementing the Sensor Web

Tsunami Warning Buoy, Fig. 11 Technical concept of GITEWS. (From website GITEWS 2018)

Enablement (SWE) standards and services (Fleischer et al. 2010).

Envirtech Tsunami Detection Buoys

The Tsunami Warning System (TWS) designed by Envirtech (website see (Envirtech Tsunami Buoys 2018)) is composed of the following main subsystems (as shown in Fig. 13):

- an underwater module (UM) to be installed at the sea bottom in open sea location for the accurate measurement of the tide and the identification of anomalous conditions,
- a surface buoy (SB) moored close to the UM to receive via acoustic link the measurement of UM to be transferred via satellite link to a data center (DC) for visualization and analysis,
- a data center (DC) on land composed of hardware and software infrastructures for the reception via satellite link of the data of SB and UM to be displayed, stored, and analyzed.

The tsunami buoy system comprises two components: the underwater module (UM), anchored to the sea floor, and the surface buoy (see Fig. 14). The surface buoy is composed of three main parts: a subsurface pole, a float (cone + cylinder) in the

Tsunami Warning Buoy, Fig. 13 Tsunami Warning System (TWS) designed by Envirtech. (Figure from Envirtech Tsunami Warning Buoy 2018)

middle, and a turret on the top. The sensors on the sea floor measure the change in height of the water column above by measuring associated changes in the water pressure. The water column height is communicated to the surface buoy by acoustic telemetry and then relayed via satellite to the tsunami warning center.

The underwater module detects by itself the presence of a “special” event and starts to operate in event mode. The sea level is acquired every 15 s, and collected data are transmitted to the surface each minute. In few seconds, data arrives to the control center and an alarm procedure is raised. Figure 15 shows the Sumatra event on October 2010, as collected by an Envirtech Tsunami buoy deployed in South China Sea, 2,600 km far the earthquake epicenter on a seabed 4,400 meters deep. The seismic waves reached the underwater module few minutes after the earthquake, setting it in alarm mode (Courtesy SOA –

China). No tsunami followed the event in South China Sea.

The buoy has multiple composite functions. In addition to tide and tsunami detection, the buoy can be optionally supplied with further payloads such as a complete meteorological station (single or double), an acoustic doppler current profilers (ADCP) for multicell current data collection and water quality multiparameter probe.

The MKIII has been built to remain operational during super typhoons, with sea conditions up to Beaufort 14. In 2010, the buoy proved its great strength when the super typhoon Megi crossed its mooring position in the South China Sea.

Summary

When the tsunami devastated wide areas around the Indian Ocean in December 2004, the effects and the dangers of a tsunami came into global public consciousness with extensive media

Tsunami Warning Buoy, Fig. 14 The Envirtech MKIII-002 tsunami warning buoys. (Figure from Envirtech Tsunami Buoys 2018)

T

coverage. In the memory and perception of tourists and holiday makers, seashore sites may forever bear tsunami-related dangers, resulting in the desire for effective, reliable, and easy-to-use tsunami alarm systems.

In the existing modern tsunami warning systems, Global Navigation Satellite System (GNSS) plays a central role, whether in DART system with buoys or in GITEWS without buoys. The key role in these systems is played by GPS. Thanks to the

developments made in GNSS data processing, especially in the framework of the International GNSS Service, a relatively cheap infrastructure of high-tech high-sea buoys can provide a very accurate and efficient tsunami early warning system.

One of the challenges of tsunami warning is the application of rapid forecasting, for example, the application in Indonesia, where a tsunami caused by an earthquake in Sulawesi in 2018 killed hundreds of people. A long-term goal of tsunami

Tsunami Warning Buoy, Fig. 15 Sumatra event collected by an Envirtech tsunami buoy deployed in South China Sea on October 2010. (Figure from website Envirtech Tsunami Buoys [2018](https://www.envirtech.com/Envirtech_Tsunami_Buoys.html))

assessment is to develop sensors that can detect and measure near-field tsunamis as close to the power generation area as possible. If this is achieved, countries will be able to obtain data more quickly, which could reduce evacuation times.

Definition

The underwater acoustic positioning system can be divided into long baseline (LBL), short baseline (SBL), and ultra-short baseline (USBL) or

super short baseline (SSBL) systems according to the spacing of the elements. **Ultra-short baseline** positioning system array length is generally on the order of several centimeters to tens of centimeters, usually less than or equal to half a wavelength, and the phase difference between the received signals of each array element is used to solve the spatial position of the target. All array elements form a sound array, which can be mounted at the bottom of the carrier or suspended from the side of the carrier or installed where fluid noise and structural noise are relatively weak. The ultra-short baseline system has high requirements for the installation of the acoustic array. The installation position of each array element before installation needs to be determined in advance, that is, the position deviation of the array element relative to the carrier coordinate system and the installation deviation angle of the acoustic array need to be known (Philips 2003; Vickery 1998).

The ultra-short baseline positioning system has the advantages of convenient installation, flexible use, and low system cost, but the positioning accuracy is weaker than the long baseline. Ultra-short baseline positioning systems usually choose the low-frequency or medium-frequency band. If the ultra-short baseline positioning system needs to cover the whole sea depth range, the low-frequency (8–16 kHz) or lower-frequency band is generally selected. The relationship between the operating frequency and the maximum working distance is shown in the following Table. 1.

The ultra-short baseline positioning system has two working modes, one is an acoustic response mode, and the detected target sends an inquiry

signal to each transponder, and the interrogated transponder sends back a response signal according to the received command and passes the inquiry signal, and the time difference between the response signals is used to calculate the distance. The other is the synchronous clock mode. The clock system at both ends of the inquiry and response needs to perform high-precision clock synchronization, and the distance is calculated by the time difference from the timing of the synchronization pulse to the receipt of the response signal.

Positioning Principle

Ultra-short baseline arrays have different positioning principles for narrowband and wideband received signals. When the signal transmitted by the target is a narrowband signal, the direction finding is performed by measuring the phase difference between the received signal and the different array elements; when the signal transmitted by the target is a wideband signal, the delay difference between the received signals and the different array elements is measured. Perform direction finding positioning (Han et al. 2015).

As shown in Fig. 1, the origin of the coordinate is O; the center of the array is the element 2 at the origin; the element 1 and the element 3 are located on the X and Y axes, respectively; and the distance from the center of the array is L, Z-axis. The bottom is perpendicular to the XOY plane. Let the coordinates of the target be S(x, y, z), then the following relationship:

Ultra-short Baseline Underwater Acoustic Location Technology, Table 1 Relationship between working frequency band and maximum working distance

Serial number	Band	Operating frequency (kHz)	Maximum working distance (m)
1	Low frequency (LF)	8~16	10,000
2	Medium frequency(MF)	18~36	3500
3	High frequency(HF)	30~60	1500
4	Extremely high frequency(EHF)	50~110	1000
5	Very high frequency(VHF)	200~300	100

Note: It is assumed that the noise level of the shipborne acoustic transducer array is less than 95 dB in the operating band and the underwater sound source level of the underwater transponder is greater than 195 dB re1μPa@1m.

Ultra-short Baseline Underwater Acoustic Location Technology, Fig. 1 Acoustic array positioning principle

$$\cos \alpha = \frac{x}{R}$$

$$\cos \beta = \frac{y}{R}$$

$$R = \sqrt{x^2 + y^2 + z^2}$$

where α is the angle between the vector and the X-axis, β is the angle between the vector and the Y-axis, and R is the target and the center of the array.

For the projection of S on the XOY plane, its angle θ with the X-axis is the target horizontal azimuth

$$\theta = \tan^{-1} \frac{y}{x} = \tan^{-1} \frac{\cos \beta}{\cos \alpha}$$

$$R = \sqrt{x^2 + y^2}$$

$$z = \sqrt{R^2 - r^2}$$

where r is target horizontal slant distance and z is target depth.

It is assumed that the size of the array is much smaller than the distance between the target and the array, that is, $R \gg L$. At this time, it can be approximated that the target is incident from the far field, and the acoustic wave reaching each element is approximately plane-wave incidence, as shown in Fig. 2.

Ultra-short Baseline Underwater Acoustic Location Technology, Fig. 2 Coaxial two-element incident signal positioning principle

The delay difference between the array elements is satisfied.

$$\tau = \frac{L \cos \alpha}{c}$$

where c is the measured sound velocity in the sea area of the operation.

When the system uses the signal as a narrow-band signal and depends on the phase difference between the measured signal and the receiving array element, the target position is calculated (Sun et al. 2014).

$$x = \frac{\lambda \varphi_x ct}{2\pi L}$$

$$y = \frac{\lambda \varphi_y ct}{2\pi L}$$

where φ_x is the phase difference between two elements on the X-axis; φ_y is two-element phase difference on the Y-axis; and t is the one-way propagation delay of the acoustic signal from the target to the array.

When the system uses the signal as a wideband signal, the target position is calculated by using the delay difference. The actual measured value is the sum and R , which can be obtained by the response time measurement.

$$x = \frac{\lambda \tau_x R}{L}$$

$$y = \frac{\lambda \tau_y R}{L}$$

where τ_x is delay difference of signals received by two elements of X-axis $\tau_x = \frac{\cos \alpha}{L}$ and τ_y is delay difference of two signals received by Y-axis $\tau_y = \frac{\cos \beta}{L}$.

Application and Development Trends

The ultra-short baseline positioning system appeared relatively late, and reports on ultra-short baseline positioning systems were first seen in the early 1980s. After more than 40 years of continuous development, the products of a few influential companies occupy most of the world's markets. Among the more representative companies are iXblue in France, Kongsberg in Norway, Sonardyne and Nautronix in the United Kingdom, LinkQuest and EdgeTech in the United States.

France iXblue company's advantage field for marine science research, the new generation of ultra-deep long-range ultra-short baseline positioning system POSIDONIA2 maximum positioning depth of up to 7000 m, the maximum positioning slant distance of 8000~10,000 m, and positioning accuracy of 0.2% slant distance,

can be applied to deep-sea target tracking and positioning, such as ROV and AUV, and submarine tubing and cable-laying construction. The medium-range ultra-short baseline positioning system GAPS has a 3D geometric acoustic array that combines positioning with an optical fiber inertial navigation system (INS) to provide no less than 500 acoustic channels. Recently, the underwater acoustic communication function has been added to the system. In the depth roadmap mode, it can form an LBL/USBL/INS integrated navigation system together with a long baseline.

The Norwegian Kongsberg company has been engaged in the research and development of acoustic positioning systems. Its products have been applied in the field of dynamic positioning and submersible docking. The HiPAP series of ultra-short baseline positioning products have been developed. From 1996 to 2015, three generations of products were launched. HiPAP502/452/352/102 is a third-generation product that uses the same hardware and software platform and has a long baseline position function. The new communication and positioning acoustic protocol Cymbal is used in the product, and the positioning accuracy is further improved. The μ PAP series is a compact ultra-short baseline positioning system that can be operated on the surface carrier, with a built-in motion sensor and inertial navigation system. It is used for positioning requirements of ROV, tow body, diver, and other targets within 1000~4000 m underwater. The accuracy is 0.45% slant distance.

The UK's Sonardyne company's strengths are offshore oil and gas development. In 2005, it successfully launched WideBand's full range of ultra-short baseline products based on broadband digital technology. In 2010, it launched the second generation of ultra-short baseline products of 6G broadband digital technology. The main products are Mini-Ranger2, Ranger2, and Scout. The Mini-Ranger2 is a compact and portable product that can be combined with WSM6+, WRT6, and WM6 transponders. With a working range of up to 10,000 m and an accuracy of 0.1% slant distance, Ranger2 uses the unique multi-pulse stack technology to achieve data update rates of up to 1 s in any water depth

environment, supporting long baseline/ultra-short baseline combined positioning and inertial navigation. The Scout series includes Scout, ScoutPlus, and ScoutPro, which can be used for small target positioning such as ROV and tow body in the range of 500–1000 m. Nautronix products dominate the offshore drilling and mining industry. Its NASDrill-USBL is developed for use in near-shore drilling and other environments that require high noise and harsh environments. The system has a range of 4,500 m and an accuracy of 0.5% slant distance.

In 2002, LinkQuest of the United States launched the first diving ultra-short baseline positioning system TrackLink 1500, which quickly became a bestseller. The TrackLink 10,000 series developed in recent years belongs to the low-frequency remote ultra-short baseline positioning system. Based on its unique acoustic broadband spread spectrum technology, it can provide users with ultra-long-range deep-water communication and tracking and positioning solutions. EdgeTech, formerly known as ORE Marine, and ORE Marine products are TrackPoint II, TrackPoint 3, and TrackPoint 3P. EdgeTech has introduced the long-range ultra-short baseline positioning system BATS. The system is available in three configurations, portable BATS (Broadband Acoustic Tracking System), desktop BTAS, and installation. BATS can be combined with Motion Reference Unit (MRU) and heading sensor (HS) (Jin et al. 2018).

With the continuous improvement of marine survey and marine engineering requirements, ultra-short baseline positioning technology has gradually shifted from single positioning mode to integrated positioning mode, such as LBL/USBL, SBL/SUBL, and LBL/SBL/USBL systems; from acoustic positioning to acoustics positioning integrated inertial navigation positioning, Motion Reference Unit; signal system from narrowband to wideband; positioning for a small number of users to provide multi-target targets in the work area; and from single positioning function to multifunctional integration, such as integrated underwater acoustic communication; positioning accuracy is developed from the initial tens of meters to the meter.

Definition

In general, umbilical cable is a kind of integrated functional structure, whose structure is similar to a baby's helically wound umbilical cord which is widely used in aerospace field (such as between the launch pad and the vehicle or between the space suit and the vehicle), diving (such as the umbilical cable that supplies oxygen for diving suits), and ocean engineering (such as applications to ROV underwater robot and subsea production systems). The purpose of this entry focuses on the umbilical cable which is used in the subsea production systems (Drumond et al. 2018).

Subsea production system is widely used in the development of subsea petroleum, petrochemical, and natural gas industries. In general, subsea wellhead, subsea production facilities, and subsea pipeline partly or fully transmit the extracted petroleum, petrochemical, natural gas, and water to the marine-dependent facilities or end-termination interfaces, which realized the development of offshore petroleum, petrochemical, and natural gas industries. The typical subsea production system can be divided as follows: subsea well system (including wellhead and Christmas tree), production system (including manifolds, template, and protective structure), and subsea pipe system (including chemical injection pipeline, subsea umbilical cable, and riser). Compared to other ways, the subsea production system is more suitable for developing deep water, marginal petroleum, and natural gas fields for the reason that it has a huge advantage. Since subsea umbilical cable is one of the main equipments of the subsea production systems, it plays a very important role to keep the operation safe. In another word, it is an indispensable component in subsea production systems, as a lifeline between surface facilities and subsea production systems (Yue et al. 2013).

The function of umbilical cables connecting upper floater and subsea production systems is to transmit power, hydraulic power, control and feedback signals, and chemical between them. Power, hydraulic power, and chemical are usually transmitted from top to bottom in one

direction. The control and feedback signals are two-way transmissions (Kliewer 2013). The control signals are usually transmitted from top to bottom, while the feedback signals are usually transmitted from bottom to top, including all kinds of sensor signals and action status. In addition, storage and operation can be performed at specific temperatures within the service life range. Normally, the operation of the umbilical cable is resulted from the joint integration of the above functions and the operation of each component contributes to.

Scientific Fundamentals

Structure Composition

The structures of subsea umbilical cables are various, which are determined by different environments and functions together. In most cases, there is no existence of unified standard or style. In general, the components of umbilical cables can be classified into two categories: One is the functional components, including the electrical cables, optical fibers, thermoplastic hoses, metallic tubes, and polymeric sheath (Hardee 2010). Another one is the strengthening components, including the carbon fiber rod, armor steel wires, and fillers. Thereinto, electric cable component is mainly used for the transmission of power and control. In addition to electrical communication, it can also be used for signal transmission. Optical fiber component is mainly used to transmit all kinds of signals, which is also used to monitor the status information of the umbilical cable under special circumstances. Pipe component contains different kinds of pipelines, such as steel pipes and hoses, which is used to transmit hydraulic fluid, chemical, petroleum, and natural gas. Filler is used to fill the void and fix the relative position of each component of the umbilical cable (Tang et al. 2014). Armor layer is usually placed outside the umbilical cable, whose function is to improve the axial stiffness and strength of the umbilical and enhance the stability of the subsea umbilical cable with more weight per length. Polymeric sheath is usually wrapped outside electric cables, optical fibers, and other types of pipelines.

Umbilical Cable,
Fig. 1 The structure of
umbilical cable

Umbilical Cable,
Fig. 2 The three-
dimensional structure of
umbilical cable

The function of sheath is to insulate and protect the umbilical cable (Lu et al. 2017) (Figs. 1 and 2).

Electric Cable

Electric cable is made up of conductor, insulation, and sheath, and sometimes there is also armor and shield included. Electric cable includes power cable and signal cable. Insulation layer provides dielectric strength and electrical insulation (Beaudonnet et al. 2013). Electric cable component is covered with sheath, which protects the cable component, makes the cable round, and adjusts the size and weight. Shield layer mainly has the function of shielding the magnetic field, while the armor mainly plays the role of enhancement (Yang et al. 2015).

Hydraulic Pipe

As a result of different functions of the umbilical cables, hydraulic pipe has different structures, sizes, numbers, and positions. The subsea umbilical cables with steel pipe components are usually used in deepwater ocean due to the much stronger resistance to internal and external pressure

compared with the thermoplastic hoses (Chitwood 2006). Most steel pipes are covered with plastic layers, which can prevent cushion and wear between steel pipes and other components or steel pipes.

Optical Fiber

Optical fiber is the most important carrier of communication transmission. There are one or more optical fiber components in the umbilical cable. In general, optical fiber cores are no more than 12 cores. The fiber is suspended in a thixotropic ointment, which can prevent water, keep the fiber position stable, and protect the fiber to the maximum extent at the same time. The stability of light attenuation is maintained in various mechanical and environmental conditions (Williams et al. 2002). The fiber protection tubes are usually high-strength stainless steel tubes with high resistance to lateral pressure and corrosion, while the steel pipe is surrounded by one to two layers of steel wire which is used to enhance the tensile strength of optical fiber cable. The optical fiber cable is covered with sheath, which protects the

fiber cable, making the cable round, adjusting the size and weight, and preventing corrosion and cushion.

Sheath

Sheath can be classified into the inner sheath and the outer sheath. The function of the inner sheath is to make the cables round, provide mechanical buffering, reduce friction and anticorrosion, and keep the structure of the umbilical stable. The outer sheath is the last line of defense of the umbilical. In addition to the likeness of the influences of the inner sheath, the outer sheath also has high anticorrosion performance, UV, and seawater resistance. In some umbilical cables, the outer sheath also has the resistance to mold and marine life (Dupont et al. 2002).

Armor Layer

Different armor types can be chosen according to different uses, environments, and working conditions of the umbilical cables, such as single round steel wire, double (quadruple) round steel wire, and double (quadruple) flat steel wire. Steel wire mainly plays the role of enhancement, providing the ability of tensile, anti-torsion, and anti-pressure for the umbilical cables. At the same time, steel wire also plays a shielding role, which is mainly to shield the magnetic field. Single round steel wire is seldom used, which is mainly used in shallow sea or river where the tension is not high. The advantage of this armored method is the lightness and softness, while the disadvantage is that the tensile strength and resistance are poor. When pulled, the torsion will appear. Different from armored method, the winding direction of the double wire layer is opposite in double (quadruple) round steel wire, so it can keep the torsion balance. Compared with double (quadruple) round steel wire, double (quadruple) flat steel wire has its advantage of reducing the outer diameter of cable and increasing the tensile resistance of umbilical cables. The disadvantage of it is that the cable is so hard that the bending performance is poor. So, we can further combine flat steel wire and round steel wire, which has the advantage of high tensile strength and resistance. Even though the weight is heavier,

it is suitable for high mechanical external force (Lu et al. 2017).

Filler and Wrap

The roles of filler are mainly reflected in the following aspects. Firstly, the filler makes the umbilical cable round, which is convenient for the latter process and which is helpful for external strengthening of components. Secondly, the filler improves the tensile strength of the umbilical cable and reduces the friction between the functional components and the layers. Thirdly, the filler can improve the stability of the structure of the umbilical cable and can be used for water resistance material and can be wrapped around the block.

Classification

In general, umbilical cables contain different component types and specific numbers, according to the actual demand of petroleum and natural gas field engineering, the existing facilities and reserved equipment, and users' requirements. Therefore, it can be concluded that umbilical cable is a typical custom product (SoDahl and Ottesen 2011).

According to the difference between the umbilical cables with pipe component, it can be classified into the umbilical cable with steel tubes and with hoses. According to whether the armor layer is included, it can be divided into the umbilical cable with armor layer and without armor layer. According to the different armor materials, it can be divided into metal armor and nonmetal armor umbilical. According to the application condition of umbilical cables, it can be divided into static and dynamic umbilical cables. There are four common types of umbilical cables as the following:

Single Armor Layer Umbilical Cable with Electric Cable, Optical Fiber, Hydraulic Fluid, and Steel Tube

This type of umbilical cable is capable of transmitting power, control, communication, optical communication, hydraulic power, and chemical simultaneously. And the armor layer is made up of round steel wire (Pesce et al. 2010). There is an

inner sheath and outer sheath inside and outside the armor layer, which is suitable for the subsea production systems with electrohydraulic compound control method.

Double Armor Layer Umbilical Cable with Electric Cable, Optical Fiber, Hydraulic Fluid, and Steel Tube

The function of this type of umbilical cable is the same as the single armor layer one. What makes a difference is that there are two layers of flat steel wire in this type of cable with only one outer sheath and lining inside. It is also suitable for the subsea production systems with electrohydraulic compound control method.

Electrohydraulic Compound Umbilical Cable with Hose

This type of umbilical cable is armored by five layers of round steel wire. The armor can withstand tensile load, increase subsea stability, and protect the internal structure of the umbilical. It is suitable for the subsea production systems with electrohydraulic compound control method. Due to the permeability and self-expansion of the hose, it is suitable for short control distance and low hydraulic requirement particularly.

Electrohydraulic Compound Umbilical Cable with Steel Tube

This type of umbilical cable is suitable for the subsea production systems with electrohydraulic compound control method, which is similar to the one with hose. What is different is that this umbilical cable is composed of hose or tube (Zhu et al. 2015).

Property of Umbilical Cable

Functional Performance

As is mentioned above, the umbilical cables are for the operation demand to meet the corresponding function. Therefore, there is a demand of design indicators in the process according to each function in the production systems. Its design indicators correspond to the functional components (electric cable, optical cable, and hydraulic pipelines). The performances of electric cable and optical cable can be explained

in detail by referring to corresponding entries (Witz and Tan 1995). And the performances of hydraulic pipelines are permeability, corrosion resistance, volume expansion, compatibility, and clean ability.

Mechanical Property of Umbilical Cable

In addition to meeting the above executive functional indicators, the strengthening design of umbilical cable needs to consider the corresponding mechanical safety guarantee to ensure the normal operation of other functional components. The mechanical properties of umbilical cables are as follows:

1. Stiffness

Structural stiffness is called stiffness for short, which has the ability of structure or component to resist deformation. As an important part of the submarine production system, umbilical cable has undertaken various external static and dynamic loads in the marine environment, such as gravity load, wind load, current load, and wave load. These loads on the umbilical cable are as forces or moments (Custódio and Vaz 2002). The transportation and operation of umbilical cable depend on the stiffness of the umbilical itself. Therefore, the stiffness of umbilical cable is a quite important mechanical property which is the key to determine whether the cable can work safely in subsea production system. The main stiffness indexes of umbilical cable are tensile stiffness, torsional stiffness, and bending stiffness. The axial tension and torque are coupled, due to the helical structure in umbilical cable. When there is axial displacement, axial elongation and torsion can occur simultaneously. The relationship between the force and displacement is shown as follows:

$$\begin{bmatrix} F \\ M_t \end{bmatrix} = \begin{bmatrix} k_{11} & k_{12} \\ k_{21} & k_{22} \end{bmatrix} \begin{bmatrix} \frac{\Delta L}{L} \\ \frac{\Delta \theta}{L} \end{bmatrix} \quad (1)$$

In the formula, F represents the axial tension, M_t represents the torque, ΔL represents the

axial elongation, $\Delta\theta$ represents the torsion angle, and L represents the length of umbilical. k_{11} , k_{22} are tensile and torsional stiffness. k_{12} , k_{21} are interaction stiffness. In particular, balance of torsion should be considered during installation to avoid damage because of torsion knotting or torsion accumulation (Skeie et al. 2012).

Umbilical cables have complex structures which are made up of multiple layers of materials and formed by cross-wound laying of different angle components. Due to the unbonded mode of each structural layer of umbilical cable, there will be relative sliding between each structural layer and a lot of contact interface and interface friction with the increase of the curvature while it bends. And the bending deformations are also inconsistent for different types of umbilical cables. Umbilical cable is usually in the full sliding state in practical engineering application. Therefore, in general, bending stiffness is estimated with complete sliding models. The greater the angle of armor winding is, the smaller the bending stiffness of umbilical cables is, the better the performance of flexible bending is.

2. Strength

Strength is the ability of a structure or component to resist damage. Being similar to the stiffness of umbilical cables, strength is another important mechanical performance. In general, hoop stress, radial stress, and axial stress are included in the stress of typical umbilical cables. The total load capacity of umbilical cable is determined by the ultimate stress state of most vulnerable components. Hoop stress, radial stress, and axial stress are usually combined by the strength yield criterion so as to check whether the stress satisfies the yield strength of the materials.

The main strength properties of umbilical cable include maximum tensile capacity and minimum bend radius. Maximum tensile capacity is the failure criterion of umbilical structure with the strain failure of different

components (such as steel tube, armor, polymer, and so on). When the maximum tensile capacity of each component is given, the minimum value of these components is taken as the maximum tensile capacity of the umbilical, which should be greater than the extreme tensile load in the application environment. It is important to ensure adequate safety margin at all operation conditions so as to ensure the normal and safe operation of the umbilical cable. In addition, buckling failure, plastic failure, and functional failure of umbilical cable will be caused by excessive bending during the storage and working operation. Therefore, minimum bend radius is also a key property for the umbilical cable design.

3. Fatigue life

During the working operation of umbilical cables, alternating tension and bending load can be generated as a result of the wave and current. As a result, the armor and steel tube are damaged by the fatigue failure. Fatigue is one of the most common failure modes for dynamic umbilical cables, which directly determines the service life of umbilical cable. Therefore, the estimation of fatigue life of umbilical cable is the most important property in the whole design process.

Ancillary Equipment

In addition to the main equipments, some ancillary equipments of umbilical are needed to ensure that the umbilical cable works normally in subsea production systems. It can be classified as ancillary equipments for connecting and for strengthening. The ancillary equipments for connecting are used to connect the cable and the upper floating body or the underwater development device and to provide functional protection, which include surface umbilical termination, pull-in head, suspension device, J-tube or I-tube seals, subsea umbilical termination, connection box, and weak link. The ancillary equipments for strengthening are used to maintain the overall layout of the umbilical cable and to provide mechanical protection for the joint, including bend stiffeners, bend

restrictors, and buoyancy attachments (Tang et al. 2014).

Key Applications

Umbilical cable is one of the main equipments of the floating production systems. As a lifeline between surface facilities and subsea production systems, it is a key component of the subsea control systems. Generally, umbilical cable is composed of electrical cable, optical fiber, thermoplastic hose and metallic tube, transmitting hydraulic, power, control signal, chemical, and so on. So far, it is widely used for the development of subsea oil and natural gas during the whole production process in shallow water, deep water, and ultra-deep water (Witz and Tan 1992).

The application of subsea umbilical cable has a history of nearly 60 years in ocean engineering. It was in the 1960s that the earliest umbilical cable appeared in a subsea wellhead in Mexico by Shell. In the 1970s, there is a system which is called electrohydraulic compound control system appeared, making it possible to reduce the cross-sectional area of subsea umbilical cable greatly. In addition to subsea hoses, it also includes power cables and data transmission lines. The early subsea umbilical cable was made of thermoplastic hoses until Sandvik used metallic tubes instead of thermoplastic hoses firstly in the 1980s, which was used in Frigg petroleum and natural gas field in northeast Norway successfully. In the twenty-first century, the demand for power increased in the subsea production systems, as the depth increased. Nexans began to develop and produce the world's first umbilical cable with a high voltage cable (24 V) for BP in 2005. Since then, in subsea deepwater petroleum as well as natural gas fields, the subsea umbilical cable which is characterized with high voltage has been widely used (Fleming et al. 2005).

Presently, about 60% of subsea umbilical cables are used in the Atlantic region, mainly in Mexico, Brazil, Norway, and Angola. And about 30% of subsea umbilical cables are used in

Southeast Asia and Oceania, mainly in Indonesia and Australia.

Definition

Underwater acoustic (UWA) communication is a technique for sending and receiving messages by sound in water. As electromagnetic waves propagate poorly in sea water, acoustics provide the most obvious medium to enable underwater communications. UWA communication is difficult due to limited bandwidth, extended multi-path, refractive properties of the medium, severe fading, rapid time variation, and large Doppler shifts. Compared to terrestrial communication, UWA communication has much lower data rates and shorter communication range.

Scientific Fundamentals

Basic System Model

A typical UWA communication system for the transmitter and receiver in the presence of UWA channels is shown in Fig. 1. Since acoustic signals have low frequency, the passband samples are often directly generated by the modulation module (Zhou and Wang 2014). After digital-to-analog (D/A) conversion, the passband signal is amplified, passed to matching circuits, and matched to the transducer. At the receiver side, the weak signal is increased in level by a pre-amplifier, filtered by a simple bandpass filter, and sampled at the passband. Finally, the bit information can be achieved by the demodulation module. From the signal processing point of view, the channel includes the imperfections of the transmitter and receiving circuits. All the modules that are lumped together are called channel

between the D/A module and analog-to-digital (A/D) module.

UWA Communication Channels

UWA communication channels are generally recognized as one of the most difficult communication media in use today (Stojanovic and Preisig 2009). Acoustic propagation is best supported at low frequencies, and the bandwidth available for communication is extremely limited. Although the total communication bandwidth is very low, the system is, in fact, wideband, in the sense that bandwidth is not negligible with respect to the center frequency. Sound propagates in the water at a very low speed of approximately 1500 m/s, and propagation occurs over multiple paths. Delay spreading over tens or even hundreds of milliseconds results in frequency-selective signal distortion, while motion creates an extreme Doppler effect. All of these factors are the key problems to be solved in UWA communication. Next, we will introduce UWA communication channels from four aspects.

Attenuation and Noise

A distinguishing property of acoustic channels is the fact that path loss depends on the signal frequency. This dependence is a consequence of absorption (i.e., transfer of acoustic energy into heat). In addition to the absorption loss, the signal experiences a spreading loss, which increases with distance. The overall path loss is given by

$$A(l, f) = (1/l_r)^k a(f)^{l-l_r},$$

where f is the signal frequency and l is the transmission distance, taken in reference to some l_r .

Underwater Acoustic Communication, Fig. 1 UWA communication system

The path loss exponent k models the spreading loss, and its usual values are between 1 and 2 (for cylindrical and spherical spreading, respectively). The absorption coefficient is $a(f)$, which can be obtained using empirical formula (Berkhovskikh and Lysanov 1982).

Noise in an acoustic channel consists of ambient noise and site-specific noise. Ambient noise is always present in the background of the quiet deep sea. Site-specific noise, on the contrary, exists only in certain places. For example, ice cracking in polar regions creates acoustic noise as do snapping shrimp in warmer waters. The ambient noise comes from sources such as turbulence, breaking waves, rain, and distant shipping. While this noise is often approximated as Gaussian, it is not white. Unlike ambient noise, site-specific noise often contains significant non-Gaussian components.

The attenuation, which grows with frequency, and the noise, whose spectrum decays with frequency, result in a signal-to-noise ratio (SNR) that varies over the signal bandwidth. If one defines a narrow band of frequencies of width Δf around some frequency f , the SNR in this band can be expressed as

$$\text{SNR}(l, f) = S_l(f) / A(l, f) N(f),$$

where $S_l(f)$ is the power spectral density of the transmitted signal. For any given distance, the narrowband SNR is thus a function of frequency.

Another important observation to be made is that the acoustic bandwidth is often on the order of the center frequency f_c . This fact bears significant implications for the design of signal processing methods, as it prevents one from making the narrowband assumption ($B \ll f_c$) on which many radio communication principles are based. Respecting the wideband nature of the system is particularly important in multichannel (array) processing and synchronization for mobile acoustic systems.

All in all, the fact that the available bandwidth depending on the distance has important implications for the design of UWA networks. Specifically, it makes a strong case for multihopping, since dividing the total distance between a source

and destination into multiple hops enables transmission at a higher bit rate over each (shorter) hop. The same fact helps to offset the delay penalty involved in relaying. Since multihopping also ensures lower total power consumption, its benefits are doubled from the viewpoint of energy-per-bit consumption on an acoustic channel.

Multipath

Multipath formation in the ocean is governed by two effects: sound reflection at the surface, bottom, and any objects and sound refraction in the water. The latter is a consequence of the spatial variability of sound speed. Sound speed depends on the temperature, salinity, and pressure, which vary with depth and location; and a ray of sound always bends toward the region of lower propagation speed, obeying Snell's law. Near the surface, both the temperature and pressure are usually constant, as is the sound speed. In temperate climates, the temperature decreases as depth begins to increase, while the pressure increase is not enough to offset the effect on the sound speed. The sound speed thus decreases in the region called the main thermocline. After some depth, the temperature reaches a constant level of 4 °C, and from there on, the sound speed increases depth (pressure). When a source launches a beam of rays, each ray will follow a slightly different path, and a receiver placed at some distance will observe multiple signal arrivals. Note that a ray traveling over a longer path may do so at a higher speed, thus reaching the receiver before a direct stronger ray. This phenomenon results in a non-minimum phase channel response.

The impulse response of an acoustic channel is influenced by the geometry of the channel and its reflection and refraction properties, which determine the number of significant propagation paths, and their relative strengths and delays. Strictly speaking, there are infinitely many signal echoes, but those that have undergone multiple reflections and lost much of the energy can be discarded, leaving only a finite number of significant paths.

To put a channel model in perspective, let us denote by l_p the length of the p th propagation path, with $p = 0$ corresponding to the first arrival. In shallow water, where sound speed can be taken

as a constant c , path lengths can be calculated using plane geometry, and path delays can be obtained as $\tau_p = l_p/c$.

The surface reflection coefficient equals -1 under ideal conditions, while bottom reflection coefficients depend on the type of bottom (hard, soft) and grazing angle (Jensen et al. 1994). If we denote by Γ_p the cumulative reflection coefficient along the p th propagation path, and by $A(l_p, f)$ the propagation loss associated with this path, then

$$H_p(f) = \frac{\Gamma_p}{\sqrt{A(l_p, f)}}$$

represents the frequency response of the p th path. Hence, each path of an acoustic channel acts as a low-pass filter, which contributes to the overall impulse response,

$$h(t) = \sum_p h_p(t - \tau_p),$$

where $h_p(t)$ is the inverse Fourier transform of $H_p(f)$.

Time Variability

There are two sources of the channel's time variability: inherent changes in the propagation medium and those that occur because of the transmitter/receiver motion. Inherent changes range from those that occur on very long timescales that do not affect the instantaneous level of a communication signal (e.g., monthly changes in temperature) to those that occur on short timescales and affect the signal. Prominent among the latter are changes induced by surface waves, which effectively cause the displacement of the reflection point, resulting in both scattering of the signal and Doppler spreading due to the changing path length.

It is beyond the scope of the present treatment to summarize what is known about the statistical characterization of these apparently random changes in the channel response. Suffice it to say that unlike in a radio channel, where a number of models for both the probability distribution (e.g., Rayleigh fading) and the power spectral density of

the fading process (e.g., the Jakes' model) are well accepted and even standardized, there is no consensus on statistical characterization of acoustic communication channels. Experimental results suggest that some channels may just as well be characterized as deterministic, while others seem to exhibit Rice or Rayleigh fading (Chitre 2007). However, current research indicates K-distributed fading in other environments (Yang and Yang 2006). Channel coherence times below 100 ms have been observed (Preisig 2007) but not often. For a general-purpose design, one may consider coherence times on the order of hundreds of milliseconds. In the absence of good statistical models for simulation, experimental demonstration of candidate communication schemes remains a de facto standard.

The Doppler Effect

The motion of the transmitter or receiver contributes additionally to the changes in channel response. This occurs through the Doppler effect, which causes frequency shifting as well as additional frequency spreading. The magnitude of the Doppler effect is proportional to the ratio $a = v/c$ of the relative transmitter-receiver velocity to the speed of sound. Because the speed of sound is very low compared to the speed of electromagnetic waves, motion-induced Doppler distortion of an acoustic signal can be extreme. Autonomous underwater vehicles (AUVs) move at speeds on the order of a few meters per second, but even without intentional motion, underwater instruments are subject to drifting with waves, currents, and tides, which may occur at comparable velocities. In other words, there is always some motion present in the system, and a communication system has to be designed taking this fact into account. The only comparable situation in radio communications occurs in low Earth orbiting (LEO) satellite systems, where the relative velocity of satellites flying overhead is extremely high (the channel there, however, is not nearly as dispersive). The major implication of motion-induced distortion is on the design of synchronization and channel estimation algorithms.

The way in which these distortions affect signal detection depends on the actual value of factor

a. For comparison, let us look at a highly mobile radio system. At 160 km/h (100 mph), we have $a = 1.5 \times 10^{-7}$. This value is low enough that Doppler spreading can be neglected. In other words, there is no need to account for it explicitly in symbol synchronization. The error made in doing so is only 1/1000 of a bit per 10,000 bits. In contrast to this situation, a stationary acoustic system may experience unintentional motion at 0.5 m/s (1 knot), which would account for $a = 3 \times 10^{-4}$. For an AUV moving at several meters per second (submarines can move at much greater velocities), factor a will be on the order of 10^{-3} , a value that cannot be ignored.

Non-negligible motion-induced Doppler shifting and spreading thus emerge as another major factor that distinguishes an acoustic channel from the mobile radio channel and dictates the need for explicit phase and delay synchronization in all but stationary systems. In multi-carrier systems, the Doppler effect creates particularly severe distortion. Unlike radio systems, in which time compression/dilation is negligible and the Doppler shift appears equal for all subcarriers, in an acoustic system each subcarrier may experience a markedly different Doppler shift, creating non-uniform Doppler distortion across the signal bandwidth.

Modulation Schemes

Incoherent Modulation

Most early UWA communications systems used incoherent modulation methods for reasons of simplicity and reliability (Chitre et al. 2008), such as binary frequency-shift keying (2FSK), whose modulation process is presented in Fig. 2. Frequency-shift keying (FSK) is a frequency modulation scheme in which digital information is transmitted through discrete frequency changes of a carrier signal. However, there were a number of exceptions, in particular systems that were used in channels with little boundary action, for example, vertical links in deep water. Vertical links using directional transducers on unmanned underwater vehicles (UUVs) and ships are very clean, experiencing little or no delay spread, with the result that the biggest challenge is tracking the carrier phase that changes with respect to range.

Underwater Acoustic Communication, Fig. 2 Incoherent modulation (2FSK)

Underwater Acoustic Communication, Fig. 3 Coherent modulation (2PSK)

Coherent Modulation

A typical coherent modulation process (binary phase-shift keying, 2PSK) is shown in Fig. 3. Binary phase-shift keying (2PSK) is a digital modulation process that conveys data by changing (modulating) the phase of a constant frequency reference signal (the carrier wave). Through the 1980s phase, coherent communication was used almost exclusively for deep water vertical links, but in the early 1990s phase, coherent communication in multipath channels began to attract attention, as incoherent methods were limited to a bandwidth efficiency of approximately 0.5 bits per Hz.

Single Carrier Modulation

One major step toward high rate communication is single carrier modulation of information symbols from constellations such as phase-shift keying (PSK) and quadrature amplitude

modulation (QAM), whose block diagram is shown in Fig. 4 (Zhou and Wang 2014). With symbols $s[i]$ and pulse shaping filter $p(t)$, the transmitted signal is

$$x(t) = \sum_{i=-\infty}^{\infty} s[i]p(t - iT),$$

where T is the symbol period. The corresponding passband signal can be obtained by

$$\tilde{x}(t) = 2 \operatorname{Re} \{x(t)e^{j2\pi f_c t}\}.$$

The channel introduces intersymbol interference (ISI) due to multipath propagation. When data symbols are transmitted at a high rate, the same physical channel leads to more channel taps in the discrete-time equivalent model. Advanced signal processing at the receiver side is used to suppress the interference; this process is termed channel equalization. Although widely used for slowly-varying multipath channels in radio applications, channel equalization for fast-varying UWA channel is a significant challenge.

Multi-carrier Modulation

Multi-carrier modulation offers an alternative to a broadband single carrier communication. By dividing the available bandwidth into a number of narrower bands, orthogonal frequency-division multiplexing (OFDM) systems can perform equalization in the frequency domain and eliminate the need for complex time-domain

equalizers. The OFDM modulation process is described in Fig. 5. OFDM modulation and demodulation can easily be accomplished using fast Fourier transforms (FFT). A shallow water experiment in the Mediterranean Sea yielded good OFDM performance ($\text{BER} < 2 \times 10^{-3}$) at ranges by to 6 km (Frassati et al. 2005). At the same ranges, the DSSS performance was found to be significantly poorer.

OFDM systems often use a guard period (often implemented as a cyclic prefix or zero prefix) between consecutive OFDM symbols to avoid ISI. When the delay spread is long, the prefix length can significantly affect the bandwidth efficiency. Maximum likelihood sequence detection (MLSD) on individual subcarriers using a low complexity PSP can combat ISI when the symbol period is smaller than the delay spread (Morozov and Preisig 2006). Other channel shortening techniques such as sPRE may also be used in future OFDM systems to reduce the prefix length and improve bandwidth efficiency.

When using coded OFDM, consecutive symbols are often striped across subcarriers to reduce the error correlation due to fading. However, impulse noise present in some environments can affect multiple subcarriers simultaneously and hence generate correlated errors. The use of a channel interleaver with coded OFDM allows symbols to be distributed over frequency-time plane, thus allowing the code to make maximal use of frequency and time diversity offered by OFDM (Chitre et al. 2005). The knowledge of error correlation due to impulsive noise could be used in future decoding algorithms to improve decoding performance.

OFDM systems are very sensitive to the Doppler shift due to the small bandwidth of each subcarrier as compared to the Doppler shift. As the carrier frequency in UWA systems is typically low as compared to the Doppler shift experienced due to movement, the communication systems have to

Underwater Acoustic Communication, Fig. 4 Single carrier modulation

Underwater Acoustic Communication, Fig. 5 Multi-carrier modulation

Underwater Acoustic Communication,

Fig. 6 Spatial modulation

cope with wideband Doppler which results in non-uniform Doppler shift across subcarriers. In Stojanovic (2006), the author presents an algorithm for non-uniform Doppler compensation in OFDM systems based on a single adaptively estimated parameter. In Sharif et al. (2000), the authors present a preprocessor that estimates Doppler shift by measuring the time between two known signals and removes the Doppler shift using a computationally efficient linear interpolator. Being a preprocessor, the technique can be used with any type of modulation and equalization.

Spatial Modulation

The process of spatial modulation (SM) is shown in Fig. 6. Information theoretic studies have shown that the capacity of a channel increases linearly with the minimum of the number of transmit and receive antennas. This increase in capacity translates to a corresponding increase in achievable data rate through the use of multiple input multiple output (MIMO) processing techniques and space-time coding.

Optimal detection techniques such as MAP and maximum likelihood sequence estimation (MLSE) exponentially grow in terms of complexity with the number of antennas. To address this problem, space-time trellis codes (STTC) and layered space-time codes (LSTC) can be used with suboptimal decoding techniques (Roy et al. 2004). The benefits of MIMO over single-input single-output (SISO) UWA communication systems were successfully demonstrated through an experiment in the Mediterranean Sea using two transmit projectors for STTC and four transmit projectors for LSTC. In another set of experiments

with six transmit projectors, a spatial modulation scheme with an outer block code, interleaver, and an inner trellis-coded modulation (TCM) was demonstrated (Kilfoyle et al. 2005). The experiments demonstrated that the proposed spatial modulation scheme offered increased bandwidth and power efficiency as compared to signals constrained to temporal modulation. For ISI-limited channels, spatial modulation offers the possibility of increasing data rates when simply increasing transmission power does not. In a MIMO-OFDM experiment, the nearly error-free performance was achieved with a 2-transmitter 4-receiver setup at ranges up to 1.5 km using a $\frac{1}{2}$ -rate low-density parity check (LDPC) code at a coded data rate of 12 kbps (Li et al. 2007).

Key Applications

As efficient communication systems are developing, the scope of their applications continues to grow, and so do the requirements on the system performance (Stojanovic 1999). Many of the developing applications, both commercial and military, are calling for real-time communication with submarines and AUVs, UUVs. Setting the underwater vehicles free from cables will enable them to move freely and refine their range of operation. The emerging communication scenario in which the modern UWA systems will operate is that of an underwater data network consisting of both stationary and mobile nodes. This network is envisaged to provide an exchange of data, such as control, telemetry, and eventually video signals, between many network nodes. The network nodes, located on underwater moorings, robots,

and vehicles, will be equipped with various sensors, sonars, and video cameras. A remote user will be able to access the network via a radio link to a central node based on a surface station. Moreover, UWA communication plays a crucial role in the frogman information system. Compared with other communication forms such as electromagnetic waves, UWA communication has a longer operating range and more reliable performance.

Definition

Underwater acoustic sensor network is composed of sensor nodes placed on the seabed and in the sea (including fixed sensor nodes and mobile platforms loaded with sensors), sea surface buoy nodes, and two-way acoustic links between them, which could cover a large area of underwater three-dimensional areas. Underwater acoustic sensor network can collect, process, classify, and compress information, and the information could be relayed back to the land-based or ship-based control center through underwater acoustic sensor network node.

Scientific Fundamentals

Underwater Acoustic Sensor Network Architecture

The network architecture is a basis for designing underwater acoustic sensor network; it can be divided into the following four types.

One-Dimensional Underwater Acoustic Sensor Network

One-dimensional underwater sensor network is composed of a single underwater acoustic communication unit; these underwater acoustic communication units collect the required information, process the collected information, and send it to the surface buoy or base station. This underwater acoustic communication unit can be a relatively fixed unit such as a seabed fixed node or anchor node; it can also be a mobile underwater acoustic node, AUV, and other underwater units with certain mobility. One-dimensional underwater acoustic sensor network usually adopts a star network topology, and the data is transmitted in a single hop between the network unit and the remote station on the surface.

After these independent hydroacoustic units have collected information, the collected information is processed, and then sent to the surface buoy or base station. This underwater acoustic communication unit can be a relatively fixed unit such as a seabed fixed node or anchor node; it can also be an underwater mobile node, AUV, and other

underwater units with certain mobility. Due to the networking architecture and task requirements, the one-dimensional underwater acoustic sensor network usually adopts a star network topology, and the network unit and the remote station on the surface adopt a single-hop method to transmit data.

Two-Dimensional Underwater Acoustic Sensor Network

Different from one-dimensional underwater acoustic sensor network, two-dimensional underwater acoustic sensor network consists of multiple underwater acoustic communication nodes. All nodes in the network are at the same depth underwater. Usually, the nodes in the network are divided into two categories, ordinary nodes and sink nodes. Ordinary nodes only have horizontal communication capabilities, not vertical communication capabilities. The ordinary node collects and processes the required information and sends the data to the sink node through the horizontal link. The sink node has both horizontal and vertical communication capabilities. Sink nodes receive data packets from ordinary nodes through the horizontal link, and after processing, upload the data packets to the surface buoy or base station through the vertical link. Surface buoys or base stations upload data to satellites or send data to shore-based command centers through radio frequency communication. Two-dimensional underwater acoustic sensor network constitutes a variety of network topologies such as star, grid, or ring according to the needs of the tasks performed.

Three-Dimensional Underwater Acoustic Sensor Network

Different from two-dimensional underwater acoustic sensor network, the nodes in three-dimensional underwater acoustic sensor network are not completely at the same depth underwater. Three-dimensional communication can be carried out between network nodes. Nodes of different depths are clustered according to their depths, and nodes of the same or similar depth are clustered in the same cluster. Nodes have both horizontal and vertical communication capabilities.

physical layer	physical layer	

Nodes can communicate with nodes in the same cluster through horizontal links or communicate between clusters or with surface buoys or base stations through vertical links.

Four-Dimensional Underwater Acoustic Sensor Network

Four-dimensional underwater acoustic sensor network is composed of a static three-dimensional underwater acoustic sensor network and mobile underwater mobile acoustic communication units. Mobile underwater acoustic communication units include AUVs, mobile nodes, etc. The information collected by the static network can be sent to the mobile underwater acoustic communication unit, and then sent to the surface buoy or base station through the mobile acoustic communication unit. Since the mobile acoustic communication units in four-dimensional underwater acoustic sensor network have good mobility, the underwater acoustic sensor network of this structure can also combine optical communication and radio communication to meet more different needs.

Layered Network Model

Compared with land-based radio communication network, the research on underwater acoustic sensor network is still in its infancy. From the perspective of practical application, in order to reduce the complexity of network design, referring to the open systems interconnection (OSI), model, and transmission control protocol/internet protocol (TCP/IP) proposed by the International Organization for Standardization, underwater

acoustic sensor network is mainly divided into the physical layer, data link layer, and network layer, as shown in Fig. 1. The details are as follows:

Physical Layer

Physical layer is responsible for realizing the modulation and demodulation of information flow data. Its main function is to provide transmission media and interconnection equipment for data communication between nodes, and to provide a reliable environment for data transmission. Modulation is performed at the transmitting end, and the digital information represented by “0,” and “1” is modulated into an acoustic signal for propagation in the underwater acoustic channel. At the receiving end, the received acoustic signal is demodulated, and the original bit stream information is restored. Physical layer only transmits digital modulation information composed of “0” and “1” and does not care about the specific meaning of each bit.

The goal of the physical layer communication algorithm is to improve the reliability and effectiveness of the communication system as much as possible. Because the multipath effect of the underwater acoustic channel causes signal amplitude fading and inter-symbol interference, the channel bandwidth is limited (Stojanovic and Preisig 2009). The main technologies currently used in the underwater acoustic sensor network physical layer include phase shift keying (PSK), multiple frequency shift keying (MFSK), and orthogonal frequency division multiplexing (OFDM). In addition, in order to achieve robust

underwater acoustic communication, the key technologies commonly used in underwater acoustic communication include decision feedback equalization technology, time reversal mirror technology, sparse channel estimation and equalization technology, and wideband doppler compensation technology.

Data Link Layer

Data link layer is the middle layer of underwater acoustic sensor network, and its goal is to achieve fair and effective sharing of underwater acoustic channel resources by each network node. When designing the data link layer, while pursuing high throughput, minimize signal delay, and node power consumption. The design and implementation of the MAC protocol is the main research content of the data link layer of the underwater acoustic sensor network. The design of a MAC protocol with high efficiency, high throughput, and low energy consumption is very important to improve the performance of the underwater acoustic sensor network. Although there are many classic, mature, and efficient MAC protocols for land-based wireless sensor network, due to the big differences between underwater acoustic sensor network and land-based wireless sensor network, the MAC protocol suitable for land-based wireless sensor network cannot work efficiently in the underwater acoustic sensor network, and the MAC protocol needs to be designed according to the characteristics of the underwater acoustic sensor network.

MAC protocols in underwater acoustic communication are usually divided into two categories, namely, scheduled-based and random competition (Climent et al. 2014). The scheduled-based MAC protocols mainly include time division multiple access (TDMA), frequency division multiple access (FDMA), and code division multiple access (CDMA) protocols. Random competition protocols mainly include ALOHA, carrier sense multiple access (CSMA), multiple access with collision avoidance (MACA), etc. Due to the complex application scenarios of underwater acoustic sensor network, sometimes a single multiple access technology cannot achieve good

results, and different multiple access technologies should be used in combination.

Network Layer

Based on the data link layer providing the transmission function of data frames between two adjacent nodes, the main role of the network layer is to further manage the data communication in the network, through several intermediate nodes, and try to transfer data from the source node to the destination node. Its specific functions include addressing and routing, connection establishment, maintenance and termination, etc. Each node in the network must work together to complete the route selection.

The design goals of routing protocols are mainly fast, accurate, and efficient have good scalability, and can quickly find routes. As the topology of underwater acoustic sensor network often changes, routing protocols also could quickly establish routes according to network topology changes (Domingo 2011). While selecting the best path according to the congestion of the network, the control information of maintaining routing should be minimized to reduce the overhead of routing protocol.

Evaluation Index

Evaluation of the performance of underwater acoustic sensor network mainly uses indicators such as average end-to-end delay, throughput, packet loss rate, and overload.

End-to-End Delay

End-to-end delay refers to the average time required from the sending node to the destination node to successfully receive the data packet – the unit is s. End-to-end delay generally consists of three parts: the time the application layer generates the data packet and the time the data packet waits in the cache queue; the time it takes for the data packet to be transmitted and received in the transmitter and receiver; and the time of data packet transmission in the channel.

Throughput

Throughput refers to the ratio of the amount of data packets successfully received to the unit simulation

time; the unit is bps, which is represented by TP in this entry and can be expressed as

$$TP = (Num_{pr} \times p_{size}) / T$$

where Num_{pr} is the number of successfully received data packets, p_{size} is data package size, and T is simulation time. The average throughput is used to evaluate the efficiency of underwater acoustic sensor network data transmission. The higher the throughput, the greater the amount of data transmitted per unit time, and the better the performance of underwater acoustic sensor network.

Packet Loss Rate

Packet loss rate refers to the ratio of lost data packets to the total number of data packets sent in the network, used to evaluate the stability of the underwater acoustic sensor network. It is represented by L_{rate} in this entry and can be expressed as

$$L_{rate} = (Num_{lt} \times Num_{st}) \times 100\%$$

where Num_{lt} is the number of lost data packets and Num_{st} is the total number of data packets sent in the network.

Overload

Overload refers to the ratio of the total amount of data generated by the network protocol control message to the unit simulation time; the unit is bps, which is represented by S in this entry and can be expressed as

$$S = Num_c \times c_{size} / T$$

where Num_c is the number of control packets successfully received, c_{size} is control package size, and T is the simulation time. The greater the overload, the more energy is consumed. Therefore, the overload should be reduced as much as possible when designing the network protocol.

Simulation Tools

In order to evaluate the performance of underwater acoustic sensor network, it can usually be quantitatively evaluated through simulation or

experiment. Underwater acoustic sensor network tests usually require a lot of preparation work and need to wait for suitable sea conditions and other test conditions, which require a lot of manpower and material resources, and due to the limitations of funds and sea conditions, the network performance test verification is not comprehensive. Software simulation is an effective tool for network performance evaluation. There are many software for network simulation, such as NS2, NS3, and OPNET.

NS2

NS2 is an open-source network simulation software based on the split model developed by the University of California, Berkeley. It has the characteristics of expansion and high efficiency. It can work under Windows, Linux, Unix, or Machintosh operating systems. When using NS2 for network simulation, two programming languages are generally used: C++ and OTcl. The former is used to implement the various modules of the network protocol stack, and the latter is used to write some modules and simulation scripts to configure the network topology, protocol stack, simulation time, and other parameters. The simulation results output by NS2 can be further analyzed using related tools. For example, network animator (NAM) can be used to generate a dynamic network topology map, which can clearly show the process of data packet transfer in the simulation process.

Although NS2 has powerful functions and can support wired and wireless network simulation, the publicly released NS2 software cannot be directly used for underwater acoustic sensor network simulation because its wireless channel model and physical layer communication module are not suitable for underwater acoustic sensor network. Therefore, some research institutions have improved the physical layer and channel based on NS2 and developed a series of enhanced versions that can be used for UACN simulation, such as Auqa-Sim, NS-MIRCLE, DESERT, and SUNSET (Petrioli and Petrocchia 2012).

NS3

NS3 is a discrete event simulation software for network systems developed since 2006, using

test			
helper			
protocols	applications	devices	...
internet		mobility	
network			
core			

Underwater Acoustic Sensor Network, Fig. 2 The structure of NS3

GNU GPLv2 open-source agreement. This software is not an extension of NS2 and does not support NS2 application programming interface functions. The structure of NS3 is shown in Fig. 2. The core module is the kernel module of NS3, which is the foundation of the entire NS3 operation and development, including scheduling module, callback module, tracking module, etc. Above the core module is the network module, which contains abstract components such as nodes, network cards, address types, sockets, and packets. The upper layer of NS3 provides helper classes for each module. When writing simulation scripts, users can ignore the details of the module implementation and use the APIs in the helper classes of each module to call the components provided by the module. Above the helper class is the test class, which contains content related to software testing in the module development process.

NS3 provides a visualization tool that can dynamically track the flow of data packets in the simulation process. As one of the cores of NS3, the data collection system allows users to easily track the data or events of interest in all directions, and finally collect and visualize output through the interface provided by the system. NS3 is still under continuous development and improvement. The publicly released version includes a simple underwater acoustic sensor network model (Tracy and Roy 2008) that can simulate the MAC protocol of centralized underwater acoustic sensor network.

OPNET

OPNET is a commercial discrete event network simulation software, which uses a three-layer

model of process model, node model, and network model to simulate network behavior. The network model is the uppermost layer, which is composed of nestable subnets, communication nodes, and links for communication between nodes. The network topology and model configuration are completed at this layer; the process model is the lowest layer, using a finite state machine (FSM) describing each state and the transition relationship between states. This layer is the specific location for the realization of communication protocol function simulation and simulation-related control behavior. FSM is a communication behavior program described in C language; the node model defines the internal structure of the node, which consists of a transmitter module, a receiver module, a processor module, and a queue module.

Currently, researchers have applied OPNET to underwater network simulation. Mandar et al. (2014) used OPNET to simulate the influence of the channel on the underwater acoustic network, but the lack of reliable underwater acoustic channel model and open source underwater acoustic protocol, as well as the ability to simulate 2D underwater network and other factors limit the simulation effect of OPNET. As a commercial software, the scope of application of OPNET is not as good as the open source simulation software NS2 and NS3, but its convenient way of use is still favored by many scholars.

Key Applications

With the continuous exploitation of land resources, people’s development and competition for marine resources has become increasingly fierce. As one of the most powerful helpers for marine development, underwater acoustic sensor network has a wide range of services in both military and civilian fields. In this section, various applications of underwater acoustic sensor network will be introduced. As shown in Fig. 3, the applications of underwater acoustic sensor network can be divided into five aspects: underwater monitoring, disaster prevention and monitoring, military, assisted navigation, and sports.

Underwater Acoustic Sensor Network,
Fig. 3 Applications of underwater acoustic sensor network

Underwater Monitoring

Underwater monitoring refers to monitoring the characteristics of the waters in a designated area by deploying an underwater acoustic sensor network. The applications of underwater acoustic sensor network in underwater monitoring mainly include water quality monitoring (Faustine et al. 2014), habitat monitoring (Lopez et al. 2009), and underwater exploration monitoring (Srinivas et al. 2012).

Disaster Prevention and Monitoring

Natural disasters are usually unavoidable, and natural disasters in water are often more dangerous and cause more serious losses. Therefore, it is very necessary to establish an effective underwater natural disaster monitoring and prevention mechanism. Underwater acoustic sensor network has been widely used in the monitoring and prevention of underwater natural disasters. It is used to monitor and prevent floods (Udo and Isong

2013), underwater volcanic eruptions (Casey et al. 2010), underwater earthquakes and the resulting tsunamis, underwater oil pipeline leaks (Iwendi and Allen 2011), and other types of water disasters.

Military

The core of modern warfare is the network. As a part of the integrated land, sea, air, and space network, underwater acoustic sensor network is becoming more and more important in the military. An efficient and reliable underwater acoustic sensor network can greatly assist naval operations. Related researchers have conducted a lot of research on the military application of underwater acoustic sensor network. It has been widely used in mine detection (Williams 2010), submarine monitoring and positioning (Hamilton et al. 2010), underwater monitoring (Caiti et al. 2013), and other fields.

Assisted Navigation

The underwater environment has great unknowns, uncertainties, and randomness, and these instabilities tend to increase with the increase of depth. In such an unknown and dangerous environment, ships, boats, and even diving enthusiasts need reliable navigation mechanisms to escort them. Due to the particularity of underwater channel conditions, navigation technology on the land cannot be applied well underwater. Therefore, it is very important to design a navigation system that can work well underwater. Through the unremitting efforts of relevant researchers, underwater acoustic sensor network technology has been widely used in the field of underwater-assisted navigation (Guo and Liu 2013).

Sports

Underwater acoustic sensor network also has a very wide range of applications in water movement. These applications are slightly different from the previous types of applications. Sage et al. (2011) propose an underwater acoustic sensor network for monitoring swimmers' swimming performance. The swimming performance data monitored by the network can be transmitted to swimmers and coaches at the same time. Marshall (2015) focuses on locating swimmers in swimming pools through the underwater acoustic sensor network, and the experimental results show that this method is more accurate than traditional inertial positioning.

SPDM – Self-propelled type driving mechanism;
TSDM – Tow-sled type driving mechanism

Definition

Underwater Driving Subsystem – A mechanism or device for driving mining vehicles to carry out mining operations on the seabed.

Introduction

The driving mechanism of the deep-sea mining vehicle bears the body weight, interacts with the seabed or overlying sediments to realize the vehicle's movement on the seafloor. Studies on mining

vehicles for polymetallic nodule exploitation have been taken since the 1970s. Because of the relatively flat topography of the seabed in the polymetallic nodule mining area, as well as the mechanical properties of the surface sediment, such as high water content, small bearing strength, and shear strength, researchers have developed a variety of driving mechanisms based on different driving techniques. Typical underwater driving mechanisms include the Tow-sled type, the Archimedes spiral propulsion type, and the crawler self-propelled type.

In the late 1970s, some countries carried out sea trials of Towed type and Archimedes type mining vehicles. Although these two ways are technically feasible, they are not suitable for commercial mining due to low mineral collection rates and difficulty in avoiding obstacles. After that, the focus of researchers gradually turned to the development of crawler driving technology and mechanism.

The Tow-Sled Type Driving Mechanism (TSDM)

TSDM usually uses a sled-type bearing chassis. With the traction of the sea surface mining vessel through the lifting pipe, it is available to drive on sediments with low bearing capacity or shear force, and to cross some slopes and small obstacles. In 1978, Ocean Management Incorporated Corporation (OMI) successfully completed three mining tests at a depth of more than 5000 m using a tow-sled hydraulic mining machine (as shown in Fig. 1a) jointly developed by researchers from Germany, Japan, and the United States (ISA 2008).

The mechanism has the advantages of a simple structure and little disturbance or damage to the seabed. However, the mechanism cannot accurately control the direction of travel or avoid obstacles autonomously, and cannot travel in accordance with the predetermined track and preset speed, which will reduce the efficiency of seabed mineral resources collection and cause resource waste. Therefore, this kind of mechanism

Underwater Driving Subsystem, Fig. 1 Tow-sled type driving mechanism. (Yamazaki et al. 1999). (a) Bottom view. (b) Improved tow-sled mining vehicle

(a) bottom view

(b) improved tow-sled mining vehicle

is only suitable for the principle experiments, not for commercial exploitation.

Figure 1b shows an improved tow-sled mining vehicle used in towing mining experiment on a sea mountain with a depth of 1700 m in 1997 (Yamazaki et al. 1999).

The Self-Propelled Type Driving Mechanism (SPDM)

The self-propelled type driving mechanism is powered by the surface mining vessel through armored cables which could deliver a high

power level. According to the operator's remote-control instructions, it has the ability to drive along the preset path and control the mode with good surmounting and pass obstacles. Moreover, it can change the driving speed according to nodule abundance to maintain constant production capacity. The self-propelled type driving mechanism is mainly divided into the Archimedes spiral propulsion type and the crawler self-propelled type.

Archimedes Spiral Propulsion Type Driving Mechanism

The Archimedes spiral propulsion type driving mechanism was originally developed by the US Navy to use as a vehicle in swampy areas. In 1979, the Ocean Minerals Company Corporation (OMCO) carried out a mining test in the Pacific polymetallic nodule mining area. The mining vehicle used in the test adopted this kind of driving mechanism, as shown in Fig. 2a (Schick 1980). Figure 2b shows that the mining vehicle in the shuttle boat shape, developed by French scientists, also uses this type of mechanism (Herrouin et al. 1989).

The driving mechanism is driven by hydraulic pressure and has a simple structure. The propelling force generated by the high-speed rotation of the spiral blade in the sea mud makes the mechanism move forward or backward. Despite good traveling performance in swampy areas and snowfields, it is almost impossible to move on hard rock.

Subsequently, researchers from France, Japan, Germany, Russia, and China conducted extensive research on the Archimedes type of mechanism. After comparing with the crawler type driving mechanism, the following conclusions were drawn on its disadvantages (Wang 2015).

- (a) The Archimedes type's static depression depth is much lower than that of the crawler type, which means its bearing capacity is poor.
- (b) The traction force per vehicle weight of the Archimedes type is far less than that of the crawler type, while the driving power is far more than that of the crawler type. Also, the ratio is about 40:7.4.

- (c) It has difficulty in obstacles surmounting and turning around.
- (d) The spiral groove is easily trapped by the sediment, which will significantly affect the driving performance.

Therefore, whether the Archimedes spiral propulsion type driving mechanism is suitable for commercial mining on the soft seabed remains to be further studied.

Crawler Self-Propelled Type Driving Mechanism

The crawler self-propelled type driving mechanism adopts the mature universal construction machinery driving technology. A benefit from the large grounding area is that it can be well attached to the seabed and produce high traction. Meanwhile, its good maneuverability, as well as its small impact on the environment, makes it especially suitable for polymetallic nodule mining areas.

Crawler Driving Technology and Mechanism on Soft Sediment in Polymetallic Nodule Mining Areas

During the operation of a deep-sea mining vehicle, its driving mechanism interacts with the seabed surface sediment. On the one hand, the driving mechanism cuts and depresses the sediment. On the other hand, the sediment drives and bears the driving mechanism. Compared with land soils, seabed sediments (within 20 cm below the seabed surface) are characterized by high water content, large fluidity, low shear strength and compressive strength, and small friction angle. Within a certain range, the shear strength and compressive strength of the sediment gradually increase with the increase of depth. The deeper the driving mechanism is depressed, the greater the traction is generated. However, the driving resistance will be sharply increased if the depression depth is too large. Ultimately, it affects the driving performance and causes a great disturbance to the marine environment. This puts forward a larger emphasis on the design of the mining vehicle's driving mechanism, that is, to reasonably design the weight of the mining

Figure 4 shows the four-crawler driving mechanism of mining vehicles, respectively, developed by South Korea (a) (Sup et al. 2016) and GSR of Belgium (b) (Johan et al. 2018). These two mining vehicles have completed the sea test.

Crawler Driving Technology and Mechanism on Hard Ground and Complex Terrain

According to previous exploration data, the polymetallic massive sulfide deposits and cobalt-rich crust plate deposits at the top of the seamount

have complex micro-topographic features, and the mining compressive strength of the block ore body is no less than 20 MPa, which requires the driving mechanism of the mining vehicle to have good obstacle crossing abilities and adhesion. To develop driving technology and mechanisms of mining vehicles for polymetallic sulfide and cobalt-rich crust, it is possible to learn from some relatively mature technologies and mechanisms of heavy-duty operations in complex terrains, such as vehicles from mountainous areas, or combat vehicles. With different mining processes and test purposes, the driving mechanism developed may differ.

Underwater Driving Subsystem,

Fig. 5 Polymetallic sulfide mining vehicle. (Nobuyuki et al. 2018)

Underwater Driving Subsystem, Fig. 6 Four-crawler driving mechanisms of cobalt-rich crusts mining vehicle. (CIMR 2018)

Aiming at the commercial exploitation of polymetallic sulfide in the Sorawa-1 mining area of Papua New Guinea, Nautilus Minerals has developed a three-step process of mining area leveling, ore cutting, and particle collection in reference to the open-pit mining process. Based on this process, Nautilus has developed three operating vehicles with double crawler driving mechanisms and carried out tests underwater. The auxiliary cutter begins the work by grinding down the seafloor to make it level enough for the second piece of equipment, the bulk cutter. That machine grinds the resulting slurry up fine enough for the collection machine to suck it up before it is sent to a ship on the surface. Two four crawler mining vehicles were developed based on the mining process of cutting and collecting simultaneously, as shown in Figs. 5 and 6. In 2017, a polymetallic sulfide mining test at a depth of 1700 meters was completed in the Okinawa sea area (Ishiguro et al. 2013; Nobuyuki et al. 2018; Saekyeol et al. 2019). In 2018, a verification test of mining sampling at a depth of 2019 meters was completed in the cobalt-rich crusting contract area of the Western Pacific Ocean (CIMR 2018).

Introduction

Definition

Underwater information perception is a process of gathering sea environment and target signal with acoustic, optical, magnetic, electrical, and other sensors; processing the signal; and obtaining the characteristics of the sea environment and target. Since the sound wave can transmit for a long range in water, the acoustic information attracts extraordinary attention. The final purpose of underwater information perception is to develop ocean underwater surveillance system, understand the variation law of ocean environment, construct a transparent ocean, and help the mankind develop and utilize the ocean.

Function of Ocean Information Perception

In the era of informatization, if we humans want to study and utilize the ocean, we should first perceive the ocean, gather ocean information, and explore the law of ocean.

Ocean information involves a wide range of subjects, including all the aspects of ocean physics, ocean chemistry, ocean biology, ocean

geology, etc. Mankind has invented a variety of ocean surveillance equipment to observe the ocean, including coast-based ocean wave monitoring station, ocean meteorological station, ocean tide level station, coastal hydrophone station, high-frequency ground wave radar, etc. The buoy and ocean measuring ship are equipped with the synthesis aperture sonar (SAS), the acoustic Doppler current profiler (ADCP), the acoustic correlation current profiler (ACCP), the optical apparatus, and multiple kinds of seawater sensors. The meteorological satellite and water-color satellite are equipped with a variety of remote sensing and remote testing apparatus. The seabed-based platforms are equipped with a variety of sensors to measure the ocean dynamic parameters. All the sensors work together to sensing the ocean in three dimensions. The information is analyzed, computed, deduced, and signal processed, to form the ocean wind speed, wind direction, air temperature, air pressure, relative temperature, amount of rain, visibility, tidal wave, sea current vector, sea current profile, surface wind field, surface water temperature and salinity, profile water temperature and salinity, sea depth, ocean magnetic field, seabed configuration, evaporation flux, and the formation mechanism of atmospheric duct, the formation mechanism of sea area flow field and convergence zone, and other ocean physical knowledge library and ocean parameter knowledge library. All the knowledge of ocean environment factors forms a grand ocean ambient situation map, used for evaluating and forecasting the effect of ocean environments on all kinds of ocean exploiting activities (Fang 2005).

Functions of Underwater Information Perception

The physical fields to perceive include underwater acoustic field, ocean magnetic field, ocean electrical field, ocean optical field, etc. We are interested in the ocean environment information and target information, such as the characteristics of sea ambient noise, underwater target, and sound propagation, which are very important to underwater acoustic research and engineering applications. The ocean environment is complex and variable,

changing with area and time. The factors affecting sound propagation include the temperature-salt-depth profile, ocean current profile, turbulence, internal wave, frontal surface, sea-bottom sound speed, etc. (Ling 2013).

Ocean underwater information is of great importance in mankind's exploring activities. For example, the density discontinuity layer in seawater affects the safety of underwater vehicles. As a vehicle goes into the lower density layer, the buoyancy reduces suddenly, resulting in a sharp descent of the vehicle, which may cause serious accidents. The internal wave has effects on the controllability and safety of the vehicle. Tide waves and ocean currents may deviate the vehicle from its course.

Sound propagation characteristic is the most important factor that affects the acoustic information perception in the sea. Sound propagation in the sea mainly depends on the distribution of temperature, salinity, and density of seawater. In the deep sea, the difference in sound speed at vertical plane forms the convergence zone and acoustic shadow zone. An underwater vehicle may detect an object at a long range by making use of the convergence zone, and hide itself in the shadow zone. In the shallow sea, sound propagation is affected by meteorological and seabed conditions, which makes the propagation characteristics more complex than in the deep sea (He et al. 2015).

As a background interference to underwater information perception, the sea ambient noise has important effect on sonar operating range forecasting and sonar signal processing. Studying the characteristics of the sea ambient noise, including the time and frequency domain feature, spatial distribution, and correlation coefficient, taking full advantage of the differences between sea ambient noise and moving sound sources, to suppress the interferences, are very important to detecting moving source signal buried in strong interferences. The regularity in sea ambient noise may be exploited to estimate the relative ocean parameters, such as the surface wind speed, the amount of rain, the shipping distribution, etc. The above information is also used for the study of oceanography and ocean climate (Chen 2006).

Information perception for the moving sound sources is necessary for national defense security as well as the study of the sea environment. The moving sound sources include military ships, merchant ships, and other underwater vehicles. Information perception of underwater moving sources includes two cases. In the first case, the target passes not far away from the observer and may be looked as a dominant concentrated source, and the noise information acquired can be used for target acoustic characteristics analysis. In the other case, when the moving source is far from the observer, it actually contributes to the sea ambient noise. Usually, the contribution is within the lower frequency band below several hundred Hertz. Sometimes it reaches the frequency band above 1 kHz near a busy sea route.

Scientific Fundamentals

Underwater Information Perception System

An underwater information perception system includes shore-based sonars, ship-carried sonars, seabed-based sensor arrays, anchored buoys, floating buoys, autonomous underwater vehicles (AUVs), underwater gliders, wave gliders, unmanned surface vehicles (USVs), etc. Those systems carry sensors to observe and gather underwater information.

Ocean observing and information gathering in a great period and space is an important developing trend of ocean information perception. The rapid development of underwater unmanned system provides a wide-range underwater information perception capability with an effective approach. Underwater unmanned systems can be divided into two types: the stationary type and the mobile type. The stationary type mainly includes the seabed-based sensor array and anchored buoy, etc. The mobile type mainly includes AUVs and underwater gliders, etc. Both types have advantages and disadvantages. The mobile type is more flexible when performing a task since it can move. It can move into dangerous or sensitive areas to observe clearly at a short range. The advantage of stationary type are relatively simple in structure, having no dynamic energy expenditure,

supporting long-time observation and data recording, not generating self-noise, and observing quietly.

Structure of Underwater Information Perception System

The underwater information perception system mainly includes the carrier, central control unit, sensors, signal conditioner, data recorder, and battery. A digital signal processor (DSP) will be arranged when real-time data processing is required. A communication unit will be allocated when real-time transmission of the information is requested. The structure of an underwater information perception system is shown in Fig. 1.

The underwater information perception system can carry a variety of sensors. Sensors used to sensing acoustic signals include sonars, hydrophones, acoustic vector sensors, etc. For the purpose of making spatial directivity and improving the sensibility to weak signals, the sensors sensing the target and noise information usually operate as an array, such as the hydrophone array, magnetic sensor array, electric sensor array, etc. Sensors used to sense the attitude of a platform are magnetic compasses and pressure sensors. Sensors used to sense the ocean environment include CTD (conductivity, temperature, depth), SVTP (sound, velocity, temperature, pressure), ADCP, ACCP, DO (dissolved oxygen) sensor, ECO

(environmental characterization optics) sensors, gamma-ray sensors, etc.

The signal conditioner is used to filter and amplify sensor signals. The data recorder is used to record the collected digital signals, with a capacity of several months. The DSP is used to analyze and detect the collected signals, extract the signal features, compute the spatial distribution and motion state, and recognize the attribute of the source. The communication unit is used to transmit information among the distributed sensor nodes with the underwater acoustic modem. Sometimes the underwater information is needed to transmit to the radio data link, and the underwater acoustic/radio unit is used, or a communication buoy is released up to the surface. The mobile nodes such as the AUVs or underwater gliders can rise up to the surface, and transmit information with a radio unit.

Underwater Information Perception System of Stationary Type

An underwater information perception system of stationary type gathers information of underwater target or environment by sitting at the seabed or mooring in water.

The real-time transmission sub-buoy is a single-point moored system used to monitor ocean environment, as shown in Fig. 2. It can carry ADCPs, CTDs, vertical linear arrays, and vector acoustic hydrophones to gather environmental and sound source information. It boasts the advantages of both sub-buoy and surface buoy in that it is capable to conduct long-time continuous secret monitoring of deep-sea oceanographic environment and timely transmit the collected data to shore-based station. This highly integrated system features secrecy, robust against sabotage, and timely transmission and can be applied to early warning of ocean disaster and military attack.

The main performance index is as follows:

1. Operation depth: 4000 m, deployment depth of the mother buoy: 80~300 m
2. Effective range of current measurement and profiling: 0~500 m (double ADCP); temperature and salinity depth: 800 m

(a) Sub-buoy

(b) Releasing untethered communication buoy

- 3. Automatic alarm for unexpected surfacing of the mother buoy (with its real-time GPS location and survey data transmitted)
- 4. Underwater working life: 12 months

Underwater Information Perception System of Mobile Type

An underwater information perception system of mobile type gathers information about underwater target or environment by cruising in the sea.

Take an underwater glider, C-Glider, as an example. C-Glider, as shown in Fig. 3, is an

innovative platform used to monitor marine environment in middle-/long-distance waters. It features autonomy, real-time transmission, and mobility. It can be equipped with such sensors as CTDs, ADCPs, hydrophones, vector acoustic sensors, etc.

The main performance index is as follows:

- 1. Mass weight:<90 kg; total length:<2.2 m (without the antenna), housing diameter:<0.24 m
- 2. Measurable parameters: temperature, salinity, pressure, and current

Underwater Information Sensing Technology,

- 3. Survey depth:1200 m
- 4. Range: ≥ 1500 km @ 0.5kn; ≥ 500 km @ 1.2kn
- 5. Maximum horizontal speed:1.5kn
- 6. Communication and location: BeiDou satellite and radio, or iridium and radio

Figure 4 is the sound velocity profile and acoustic pulse signals collected with a glider (Jiang and Osler 2013).

Distributed Underwater Information Perception Network

With the rapid development of underwater sensor, autonomous processing, unmanned vehicle, communication, and network techniques, forming an area underwater information perception network with autonomous unmanned sensor nodes is the future developing trend of underwater information perception. The advantage of the unmanned sensor network is low cost, unmanned

Underwater Information Sensing Technology,

Fig. 5 Composition of distributed underwater information perception network (Ling 2013)

operation, and wide-range and long-time information collection.

A distributed underwater information perception network consists of sensor nodes, main node, and gateway node (Ling 2013), as shown in Fig. 5.

Sensor Node

The sensor nodes are used for gathering ocean environment information, processing array signals (feature analysis, extraction, detection, localization, and classification), and transmit processing results to the main node. The sensor nodes mainly consist of sensors and underwater acoustic modems. Different nodes use different sensors, including stationary arrays (e.g., shore-based sonars), retrievable arrays (e.g., vertical arrays released from moored buoys), ocean hydrologic sensors, etc.

Main Node

The main node is the core of a network. It is used to receive information transmitted from all the sensor nodes and fuse them. The other function of the main node is to manage the network, and each main node can manage tens of sensor nodes. The main node transmits the fused information to

the gateway node and receives the instructions from the command center through the gateway node.

Gateway Node

The gateway node is used to communicate with the command center to transmit and receive information. Usually the gateway node is appointed to the underwater acoustic/radio buoy, tethered communication buoys, AUVs, or underwater gliders. The command center receives the information from the gateway node, and combines with information from other ISR (intelligence, surveillance, reconnaissance) systems, to obtain a fairly complete picture of the ocean environment and the target situation.

In the view of logical function, the underwater acoustic network mainly consists of the physical layer, data link layer, and network layer. The physical layer mainly resolves the problem of effective data transmission, by utilizing acoustic propagation characteristics and selecting proper modulation mode. The data link layer mainly resolve the problem of exploiting the acoustic channel in multi-user mode, including the MAC (media access control) and error correction

Underwater Information Sensing Technology,

Fig. 6 Sketch map of Seaweb (Rice et al. 2000)

control. The network layer mainly resolves the routing problem, studying the propagation route from source to receiver, which depends on the topology structure of the network (Li et al. 2006).

As an effective approach to collecting information, the distributed underwater information perception network undertakes the tasks of intelligence, surveillance, and reconnaissance, i.e., detecting, locating, classifying, and tracking the target (Shen 2008).

A representative distributed underwater information perception network is the Seaweb, as shown in Fig. 6 (Rice et al. 2000). Off-board Seaweb nodes of various types may be readily deployed from high-value platforms including submarines, ships and aircraft, or AUVs and unmanned aerial vehicles (UAVs). The architectural flexibility afforded by Seaweb wireless connections permits the mission planner to allocate an arbitrary mix of node types with a node density and area coverage appropriate for given telesonar propagation conditions and for missions at hand. Seaweb underwater acoustic networking provides digital wireless links enabling deployable autonomous distributed systems (DADS). Gateways to manned control centers include radio links to space or shore and telesonar links to ships.

Key Techniques of Underwater Information Perception

The underwater information perception system collects data of the ocean environment and the

targets, performs characteristics analysis, signal detection, and classification, and extracts information from the complex sea ambient noise. The main key techniques are discussed below.

Signal Detection

The conventional method of signal detection includes the following procedures: Receiving signals with a sensor array, filtering and amplifying the signals, controlling signal dynamic range, digital beamforming, broadband analysis, and shallow-band analysis, detecting signals and estimating the target parameter. A representative passive sonar detection system is shown in Fig. 7 (Carter et al. 2001).

However, when it comes to unmanned autonomous detection for the sensor node, there are several restrictions: Firstly, the apertures of both stationary nodes and mobile nodes are relatively small, usually a few meters, which is very difficult for arranging large-scale array to improve the spatial gain. Second, the sea ambient background is very complex. Except for the sea ambient noise covering the weak signal, there are a large number of coherent interferences at off-shore areas. If the detection system is unable to distinguish multiple sources, it is very difficult to perceive weak signal in those complex interference background. Especially for the autonomous detection system, it is very difficult to adapt to all kinds of complex background to make a correct decision automatically. Third, the detection is limited by energy

Underwater Information Sensing Technology, Fig. 7 Generic passive sonar system for signal detection, estimation, and classification (Carter et al. 2001)

which is supplied by the battery. It is necessary to lower the system complexity and power consumption.

To resolve the problem of underwater autonomous detection in complex sea background, the array self-unfolding technology needs a breakthrough to improve the spatial gain, and the artificial intelligence technique is needed to improve the environment adaptive ability.

Target Classification

Target classification is the most challenging aspect of anti-submarine warfare with a passive sonar, especially in the shallow sea with complex topology. An acoustic intelligence operator needs several years of training to be qualified for target classification. The computer algorithm to complete this function automatically is not very effective yet. It extracts the time domain features, continuous and line spectrum, modulation spectrum, cepstrum, spatial distribution

characteristics, etc., and input them into a neural network for training and testing after purification and compression. The distributed system can provide a variety of views and enhanced features, and may be helpful, though there are still many problems left to be resolved.

Underwater Communication

In the underwater information perception network, acoustic communication is usually used to transmit information among the distributed sensor nodes, while the gateway node connecting the network to the higher level network usually uses the acoustic/radio buoy. The performance index such as data rate and error rate are seriously limited by the underwater acoustic channel. The most impressing characteristics are limited available bandwidth, long-spread multipath, fast channel fluctuation, and strong Doppler effect, which cause low communication rate, high error rate, high probability of interruption, and long

propagation delay. In some adverse hydrological conditions, the communication is unavailable since the receiving node may be in the shadow zone of the transmitting node. Furthermore, it is hard to be covert when communicating by underwater acoustic modem. The probability of being intercepted may be reduced by using directive beam and broadband coding, but it is still possible to be intercepted by energy detection. Cables are another option for communication, but their deployment remains a problem to be solved.

Underwater Network

With all the nodes interconnecting with each other, the underwater information perception system will expand the range of data transmission and surveillance area, and achieve information exchange to improve the perception ability, by connecting all the nodes to make a network. In the underwater network, MAC protocol mainly resolves the problem of sharing the channel within multiple users. Due to long propagation time delay and low data rate in underwater acoustic channel, there are serious conflictions in multiple user conditions. The TDMA master-slave mode MAC protocol to allocate the time slot in turn is usually adopted in small-scale underwater acoustic networks. Every sensor node may need to wait for a few minutes for their turn to send a message, with very low efficiency. The mixed protocol combining different multiple access modes and access protocols is the hot spot in acoustic MAC protocol study at present (Xu et al. 2016).

Poor acoustic propagation conditions also bring great difficulties to route selection. Due to the moving of some mobile nodes, and the severity of marine environment, underwater acoustic communication is prone to breakdown or temporary failure, causing the underwater network topology being highly dynamic, leading to a variable route, which needs regular maintenance. The underwater data link is unstable with high packet loss rate, making low efficiency of route construction and packet transmission, which causes retransmission repeatedly. The above two characters result in high power consumption in route maintenance.

Distributed Detection with Network

Looking from the outside, the conception of distributed detection has many advantages, and a variety of detection opportunities brought by the wide spread sensors is attractive. However, passive detection is basically restricted by signal level, noise level, and available array gain. So, comparing the large-scale and high-gain sensor arrays, how do many distributed sensors with small gain work properly to observe and detect?

On the other hand, it should be noted that it is the comprehensive detection ability of the distributed network that should be paid more attention to, rather than the detection ability of a single sensor node.

In the distributed network, AUVs or gliders may come close to a target to enhance the signal, exploiting weak signal characteristics for target classification. Since there is obvious uncertainty with a single sensor's detection performance, some form of measurement is required to optimize the sensor configuration, making the distributed network being exploited and controlled efficiently.

Definition

Lander is a general term for an autonomous and unmanned oceanography research vehicle, which descends by free-fall to the ocean floor (without remote assistance) and operates independently on the ocean floor. The platforms have the purpose of collecting physical, biological, and chemical variables over a predefined period of time. They operate independently of the surface for periods of a few days, for example, biological studies, up to a few years, for example, physical oceanography studies. After completing its mission, the lander releases the ballast weight by an acoustic signal transmitted from the surface or by a preprogrammed device. The vehicle comes back to the surface by merit of its positive buoyancy (Parker et al. 2003; Tengberg et al. 1995).

Scientific Fundamentals

The seafloor plays an important role in the regulation of the chemical composition of water masses in the oceans. Processes in sediments are important links or sinks in the biogeochemical cycles of elements in aquatic systems. Besides the seabed is the habitat for a great variety of higher organisms, and as such constitutes a distinct stratum for benthic life and consequently for numerous biological processes. The conventional approach to study these geochemical and biological processes is to collect a sediment sample from the seabed, bring it up to the surface, and scientists make observations and carry out experiments on it either on-board ship or in the laboratory. Methods that have been used to evaluate biogeochemical activity in sediments and at the sediment-water interface include direct measurements of benthic fluxes during incubations of sediment together with overlying water and measurements of solute distributions in and above sediments (Tengberg et al. 1995).

Accurate data are difficult if not impossible to obtain from the deep sea because artifacts are induced when the samples are subjected to large changes in hydrostatic pressure and (often) temperature as they are brought up to the surface. It is therefore preferable to carry out experiments and measurements directly at the seafloor (in situ). Even when working at quite shallow depths in shelf seas there is general agreement that it is preferable, if possible, to carry out experiments in situ, to avoid artifacts caused by excessive disturbance. Such studies can be carried out using benthic landers or other instruments deployed on the seafloor. When designing and using these instruments an important goal is to minimize the disturbance they cause to the seabed both during landing and operation. An additional benefit of using landers for deep seafloor studies is that, when they work properly, they are less demanding of ship time (and thus of money) than conventional sediment coring techniques. Once the lander has been deployed the ship is free to undertake other operations after until it is time for recovery (Tengberg et al. 1995).

When long-term operations are desired, lander platforms are the most economically suitable option. These stable platforms are autonomous and unmanned, oceanography research instruments to be deployed independently on the seabed over extended periods (Ferreira et al. 2014). Ocean Bottom Seismometer is a good example of these platforms, and it is a receiver for seismic signals that can be heard near the seabed. The major challenge when developing this type of instrument is to minimize the interference of the currents occurring at these depths, with the focus to receive a clean signal by the lander (Tengberg et al. 1995). Exploration of the ocean floor can bring both great business opportunities and new scientific discoveries. Therefore, it is of great interest to be able to obtain information about it at a low cost.

When designing a lander there are numerous points that need to be considered if it is to be successful in achieving its designated tasks at the seafloor. These include the methods of launching and recovery, the choice of construction materials for various components, the design, descent, and ascent speeds, the landing technique, selection of the techniques for sampling, observation, and measurement, and the choice of electronics and energy requirements.

Historical Development

The first in situ experiments on the seabed were carried out by scuba divers. Fluxes into or out of sediments have been obtained for a number of substances, by deploying a chamber on the seafloor isolating an area of sediment surface and the overlying water and then drawing discrete samples at specific times intervals for analysis in the laboratory.

Since the number of scientific manned submersibles in the world has always been, and is likely to remain limited, for most experiments, the use of submersibles for such deployments is impractical nor is it generally affordable. So, the development of autonomous free-vehicle landers is one obvious solution to solving these practical difficulties. In 1979, the HINGA lander, as a

representative of the first generation of landers, was designed to be deployed at the bottom of a mooring (Hinga et al. 1979).

Based on the combined experience gained with the early devices, the second-generation landers were developed during the 1980s, for example, the DEVol lander and the IHF lander. The USC lander was developed as a result of the need to have a device capable of making multiple flux incubations with a short turn-round, and of being deployed in a wide range of environments. The development of the BECI lander was based on the philosophy of keeping the concept as simple as possible, in reaction to the adverse experiences gained during the development of the highly complex MANOP lander (Tengberg et al. 1995).

During the 1990s, there was the third generation of landers which involved various new developments including FVGR-2 lander (Smith Jr 1987) and the GOMEX lander (Rowe et al. 1994) which was designed not only to estimate fluxes but also to attract and capture benthic organisms.

After entering the twenty-first century, the design and research of landers has entered a new era. Based on the original functions, the lander has been given more automation capabilities, such as fixed depth operation, active adjustment, automatic positioning, and rapid recovery.

Material for Lander Frames

Frame Material

An autonomous benthic lander must have a basic support frame on which is mounted the instruments, the ballast weights, the release mechanism, and the buoyancy. The main objective when constructing this frame is to keep its weight as low as possible without compromising its mechanical strength. Keeping the weight low not only makes the whole instrument easier to handle but also minimizes the need for expensive buoyancy material. While deployed the lander and its frame are exposed to relatively trivial static stresses, so the main risks of mechanical damage occur during launch and recovery.

For ease of transport and storage, particularly in containers, most constructors have designed outer frames that are readily dismantled. The material most commonly used is aluminum, which has the advantages of being relatively inexpensive and light. However, aluminum is not as strong as some other materials, for example, stainless steel, and many ships do not carry the special welding equipment required for repairs. Alternative materials for frames are stainless steel, titanium, and composite materials such as glass fiber reinforced with aramid fiber and with epoxy resin as binding material.

Regardless of metals used in constructing the frame, considerable care has to be taken if any combination of different metals is used (e.g., stainless-steel bolts in an aluminum frame, titanium pressure house in a stainless steel frame). Failure to insulate the metals from one another, by coating or painting, will result in the rapid corrosion of the metal with the lower reduction potential (Tengberg et al. 1995).

Ballast Weights

A wide range of materials is used for the ballast weights including concrete, scrap iron, cast iron, and lead. Lead has the highest density, but should be avoided because of its potential environmental impact may be serious. Scrap iron (e.g., railway waste) is cheap and easy to obtain but is awkward to use because of its irregular shape. Iron blocks cast into conical shapes are expensive but serve to minimize disturbance upon landing. Concrete ballast is best avoided, because of its density is relatively low, and its behavior in the deep-sea environment is poorly known.

Ballast weights can be fixed underneath the frame and used as footpads. Since most of the sediment suction is applied to the footpads, dropping them off allows the rest of the lander frame to escape easily to begin the ascent back to the surface. While this method of attaching ballast weights decreases the risk of a lander becoming stuck in the sediment, it is not a complete guarantee of success. One minor inconvenience of this method is that it complicates the deck handling, since either a special rack is needed or the lander

has to be rifted off the deck to attach the weights (Tengberg et al. 1995).

Descent and Landing

Descent

Currents within the oceanic water column will affect a lander during its descent and ascent and may carry it away from the desired position (Hendricks and Rodenbusch 1981). The faster a lander sinks or rises, the less it will drift out of position, rates of 0.5–1 m/s are acceptable, but this still means that a lander will take 1–2 h to traverse a water column 3,600 m deep. Another reason to maximize the descent and ascent rates is to save ship time, by minimizing the waiting time after launching and weight release, and if a lander takes too long a time to ascend, there may be problems relocating it at the surface. However, if the lander's descent rate is too fast, it is liable to cause excessive disturbance to the sediment-water interface at the measurement site. Also, it will be driven deeper into the sediment and so run the risk of the lander becoming irretrievably stuck in the bottom. Some landers have become trapped temporarily in sticky bottom sediments. Pull-out forces can be increased by adding more buoyancy, but this incurs penalties of increased cost and the need to use more ballast to attain the same descent speed (Tengberg et al. 1995).

Landing

As long as the footpads are large enough to prevent too deep a penetration of the frame in the sediment, most landers work successfully by simply crash-landing on to the bottom at a modest speed. Holes in the footpads can help to reduce the suction on lift-off. Some landing techniques have been devised to minimize the impact both to reduce disturbance of the experimental site and the risks of the lander becoming irretrievably stuck. The landing technique consists of the descent weights being suspended on ropes 0.6 m under the lander frame. When these weights hit the bottom, the lander is positively buoyant, stops about 0.1 m from the bottom (filmed during scuba diving), and then stays suspended above the

bottom. No feet are required on these landers because the frame never touches the bottom. This technique eliminates the risk of the frame getting stuck in the sediment (Tengberg et al. 1995).

Main Equipment

Microprocessors and Lander Electronics

Chamber stirring, water sampling, and measurements must all be controlled, monitored, and recorded electronically. The choice of controller varies greatly from the lander to lander depending on the design requirements. While designers may still opt to develop their systems depending on personal knowledge and experience in electronics, a wide range of microprocessors are now commercially available which are suitable for lander applications (small, good capacity, easy to program, and low energy consumption). It is essential to protect the electronics against seawater and so they have to be housed in pressure-cases, usually of aluminum, stainless steel, or titanium.

Other Equipment

Some landers have video or still cameras mounted to survey the landing and the bottom deployment. The lander has a camera inside the chamber to take photographs of animal movements on the sediment surface. Their use tends to be of greatest interest, during the initial stages of deployment when the behavior of the lander in water and on its arrival at the seafloor is poorly known.

Some chamber landers are equipped with communication systems that relay back to the ship the successful operation of all stages of the lander's performance, its landing, chamber penetration, lid closure, and lift-off. The simplest system is to release floats at particular phases of the operation to signal their successful completion but over deep water, the floats may not be spotted. Acoustic communication systems are expensive and maybe superfluous if the lander is to be deployed only for a few days. They could be of importance for status checks during long-term deployments (Glud et al. 1995).

Electrical Energy

For many of its functions, a lander requires energy. The longer the deployment, the greater the energy storage capacity is needed, which for chamber landers mostly used for stirring, so designs and components need to minimize energy consumption.

The energy can be supplied by different types of batteries. Lithium type batteries combine high capacity with small size. The nickel-cadmium batteries are generally rechargeable and can give high currents, but they tend to discharge at zero current and so they are unsuitable for long-term deployments. The batteries most widely used on landers are oil pressure compensated lead-acid batteries.

When calculating requirements for energy capacity, a very important aspect to take into consideration is that at cold temperatures most batteries lose up to half of their nominal capacity. Some constructors recommend splitting up the power supplies into several independent units and keeping high current and stable voltage supplies separated. Security systems and computer memories for data storage and programming normally have their individual energy supplies (Glud et al. 1995).

Ascent and Recovery

The need for an excess of float capacity after ballast release is an important consideration. If too little buoyancy is used, the lander may fail to pull out of the bottom so that it is either lost or has to be recovered by dredging.

Most landers have two independent systems for ballast release. Acoustically controlled releases are handy but expensive; their advantage is that using a system controlled from the surface, the time of recovery can be chosen to provide the most appropriate conditions (weather and time). Most acoustic releases produce precision time "pings" which can be used to estimate the distance to the lander and the direction the ship needs to be tuned to lessen the distance.

The greatest risk of damage to the lander (and human handlers) occurs during launching and recovery. It is very important to prevent the lander from swinging and bouncing while hanging from

a crane or A-frame. A successful launch and recovery avoiding damage to the lander is more a question of the skill of the ship crew and the sea state than of lander design. Some landers have been lost or damaged during recovery because of a lack of communication between people working on deck and the bridge (Glud et al. 1995).

Key Applications

The BENBO benthic lander, which was designed and constructed in collaboration with a commercial engineering company (Denmark), is shown in Fig. 1. The lander incorporates a number of interchangeable modules. These include (i) an enclosed chamber for determination of total

benthic community respiration and solute flux, (ii) a micro-profiling module which can insert up to four oxygen micro-electrodes and two pH micro-electrodes into the sediment to measure pore water concentrations at very high spatial resolution ($\sim 50 \mu\text{m}$ intervals), and (iii) a unit to insert DGT (diffusive gradient in thin films) and DET (diffusive equilibration in thin films) gel probes through the sediment-water interface to measure fluxes of trace metals and concentrations of major ions at a spatial resolution of $100 \mu\text{m}$ to 1.5 mm (Black et al. 2001).

Netherlands Institute of Sea Research developed the Bottom Boundary Observatory (Fig. 2), a four-meter tall lander for deep sea missions. Its structure was designed to remain on the seabed for long periods, sometimes more than 1 year. This lander is adaptable to several configurations; it can measure near-bottom salinity, currents speeds,

Underwater Lander, Fig. 4 Tsunami Warning and Early Response system of Cyprus (Gonçalves 2019)

currents directions, temperature; and it is equipped with cameras (Person et al. 2006).

Heger et al. (2007) developed a lander that can be equipped with different types of sensors, capturing images of deep-sea creatures or analyzing water quality. It is named Intensified Silicon Intensifier Target (ISIT) lander, as shown in Fig. 3, in which the purpose is to research stimulated and spontaneous bioluminescence emissions in the water column and benthic boundary layer to depths around 1000 m, as well as fauna attracted to artificial food falls.

In Fig. 4, one can see a flat shape system, called the Tsunami Warning and Early Response system of Cyprus, which is one of the offshore communications backbones. This lander belongs to the OceanWorks International's seafloor network systems (Gonçalves 2019).

Underwater Mining System

Hongyun Wu

Seabed Mining Department of, Changsha Institute of Mining Research, Changsha, China

Synonyms

CBL – Continuous Line Bucket; PTM – Passive Towed Mining

Introduction

The underwater mining subsystem is mainly used to collect ore from the seabed by underwater mining vehicles or other equipment. Since the exploration of the polymetallic nodule buried in the deep seabed was first started in the 1960s, it has now been extended to the other mineral resources such as polymetallic sulfide and cobalt-rich crusts. Correspondingly, the underwater mining technology and equipment have also been developed from a simple bucket mining subsystem to towed mining subsystem, then to shuttle subsystem and to current self-propelled mining subsystem to achieve accurate mining.

Bucket Mining Subsystem and Towed Mining Subsystem

In 1960, the technical scheme of towing cable with a bucket to obtain the nodule was put forward. Deep-sea mining test was completed to collect the nodule with the bucket mining subsystem, as shown in Fig. 1. It is difficult to obtain better economic benefits because the bucket cannot be controlled on the seafloor and a lot of resources are lost.

In 1967, continuous line bucket (CLB) mining technology scheme was put forward. The CLB system refers to all mining systems, which have been inspired by bucket chain dredging or by oceanographic chain dredges, that is, buckets have been fixed to a continuous line in the manner

Underwater Mining System, Fig. 1 Bucket to obtain the nodules in sea test (ISA 2008)

that a defined number of buckets are towed across the seafloor thus collecting loose materials at the top of the seabed (Fig. 2). In 1970, the CLB system was tested and achieved the expected results. The CLB system is simple in structure, and low in investment, and operation cost. However, the bucket and rope are easy to entangle, and the acquisition track on the seafloor is almost uncontrollable. It is difficult to avoid the cliff and obstacles on the seafloor, resulting in a low acquisition rate, large loss of resources and a great impact on the marine environment. The CLB system is proven to be unable to meet the requirements of underwater mining and has been abandoned by researchers.

Passive Towed Mining Subsystem and Towed Vehicle

The passive towed mining subsystem is composed of a towed collector, a lift pipe system, an airlift system, a pump lift system, an onboard

Underwater Mining System, Fig. 2 The continuous line bucket system (ISA 2008)

handling system, instrumentation and control system, and a test mining ship, as shown in Fig. 3a.

The collector, as shown in Fig. 3b, will be towed by a flexible hose made of hard rubber, collecting nodules with waterjet flow based on Coanda effect separating seafloor sediment, crushing nodules to desirable size distribution, and feeding them into the lift pipe.

During the sea trial in the 1970s, Ocean Management Incorporated corporation (OMI) and OMA both adopted the towed vehicle, as shown in Fig. 3. In 1997, an improved test was carried out on a sea mountain at a depth of 1700 m.

The test showed that the towed mining vehicle has the advantages of simple structure, light disturbance, and damage to the seabed, but it cannot accurately walk according to the planned mining route, low collection efficiency, large mining loss, and more difficult to avoid obstacles. Therefore, it is almost impossible to be used in industrial trial

production. OMI thinks it is necessary to turn to the research of remote-controlled self-propelled mining vehicles.

Shuttle Subsystem and Mining Vehicle

In 1972, French Academy of Ocean Development (IFREMER) began to study a technical scheme of shuttle subsystem integrating mining and upgrading.

The technical scheme of the shuttle subsystem is composed of a semi-submersible platform and several shuttle mining vehicles. Each mining vehicle is controlled by the platform through the acoustic system. The mining vehicle with zero self-weight in the water using buoyancy material is driven by Archimedes propeller to collect nodule at the sea bottom, and the ballast with equal weight to the collected nodules is discarded. Before all ballast is discarded, the collection is stopped, and the rest ballast is discarded until the weight of the mining vehicle in the water is zero. Under the action of the propeller, the vehicle rises to the semi-submersible platform to remove the nodules, replenish the ballast, and start a new round of mining.

As shown in Fig. 4, the vehicle PLA 1 is mainly composed of propeller mechanisms, thruster, storage bin, collection mechanism, buoyancy, battery power and navigation, positioning, telemetry, and remote control unit. The propeller mechanisms are four independently driven Archimedes screw propeller mechanisms. The four thrusters are to provide lifting and lowering power, control the height and trajectory, realize fluctuation, swing, and rotation. The storage bin was used for placing ballast and nodule or ballast, the buoyancy was used for balancing the self-weight in the water to be zero. The battery power was installed on both sides of the mining vehicle.

Only a small proportion of the model machine of the mining vehicle was tested in the laboratory. In December 1985, the PLA 2-6000 mining vehicle was upgraded and developed. In October 1987, a series of deep-water diving was carried out in the Mediterranean Sea, demonstrating its

Underwater Mining System, Fig. 3 Japanese passive towed mining subsystem and towed vehicle (Yamazaki and Yoshida 1999). (a) Japanese mining system for at-sea test. (b) The towed vehicle tested by OMI in the 1970s

Underwater Mining System, Fig. 5 The PLA II (Herrouin et al. 1989)

dynamic flight, landing, and movement capabilities on the seabed. See Fig. 5 (Charles et al. 1990).

The vehicle has the advantages of flexibility, good adaptability to seabed topography, small mining loss, and little impact on the production capacity of the system with the failure of one vehicle. However, each vehicle can only mine 250 tons of nodules in 8 hours, and a large amount of ballast waste rock needs to be transported from the land. Furthermore, a single vehicle may be lost. It must have a method to recover the failed single vehicle. The battery weight is too heavy. The manufacturing and operation costs are high. After the PLA 2-6000 was tested, the research of this system was abandoned.

Self-Propelled Mining Subsystem and Mining Vehicle

In the 1970s, a series of experiments to mine deep-sea polymetallic nodules were carried out mainly in the Pacific Ocean with a depth of 5000 meters. The testing results show that the self-propelled mining vehicle has outstanding advantages such as good mobility, easy to avoid obstacles, accurate acquisition path control, high recovery rate, and relatively constant output during variable speed driving. Subsequently, the mining vehicle of deep-sea mineral resources has gradually turned to the research of self-propelled mining vehicle, which is considered to be the most valuable mining vehicle for commercial mining.

The self-propelled mining vehicle is powered by a sea surface mining ship through armored cable. The operator on sea surface mining ship remotely controls the mining vehicle to operate on the seabed according to the set mining path. At present, there are mainly Archimedes spiral mining products and crawler mining vehicles verified by sea testing.

Self-Propelled Archimedes Mining Vehicle

At first, Archimedes spiral vehicle was developed by the US Navy in the swamp area. Ocean Minerals Company Corporation (OMCO) was applied to the deep-sea mining field. In 1979, OMCO led the mining test in the polymetallic nodule mining area in the Pacific Ocean.

The mining vehicle consists of a propulsion device, a mechanical collecting mechanism, a crushing mechanism, and a control specific embodiment. The propulsion apparatus adopts an Archimedes screw propulsion mechanism. The driving roller of the Archimedes screw propulsion mechanism has built-in buoyancy material to adjust the weight of the mining vehicle in the seawater. The nodule pick-up and handing mechanism of the miner vehicle include the following components: a rake type pick-up for lifting the nodules (and a selected amount of cushioning mud) from the ocean floor; a conveyor for transferring the picked-up nodules from the rake to a conveyor surface and for holding the nodules in a stabilized position on the conveyor surface while subsequently conveying the nodules first to a washer and then to a crusher; a washer for separating the nodules from the picked-up mud and for removing the mud from the conveyor surface; a stripper for removing the nodules from the conveyor surface at the inlet to the crusher; a crusher for crushing the nodules to a nodule slurry; and a pumping mechanism for pumping the nodule slurry from the miner vehicle to the buffer storage. A single, rake-type, nodule pick-up and associated nodule handling mechanism are used, and this pick-up and associated mechanism are located in the interior of the miner vehicle between the propulsion screws. The controls include electrical, electronic, and hydraulic controls. The operations that are actively controlled include initial placement of the miner vehicle in the mining area; the speed and direction of movement of the miner vehicle; the depth to which the rake of the pick-up penetrates the ocean bottom; the angle of inclination of the pick-up to the ocean bottom; the amount of soil or mud picked up with the nodules; the separation of the nodules from the soil or mud; the transport of the nodules to the crusher; the crushing of the nodules; the recovery of fines; the avoidance of obstacles; and the rejection of nodules or other objects above a certain size.

In 1979, OMCO carried out mining experiments in the polymetallic nodule mining area in the Pacific Ocean (Jin 1994).

Subsequently, scientists and technicians from France, Germany, Russia, and China conducted extensive research on the Archimedes screw propulsion mechanism. Through the comparative test with the crawler mechanism, it was found that Archimedes screw propulsion mechanism has high static indentation depth and walking power, low bearing capacity, difficulty in obstacle surmounting, and the spiral groove is easy to be covered by sediments, resulting in slipping. Although Archimedes screw propulsion mechanism has good performance on soft mud, swamp, and snow, it is almost impossible to walk on hard rock. Therefore, the Archimedes screw mechanism is still to be further studied and improved when it is actually used for driving on the thin soft seabed (Fig. 6).

Self-Propelled Crawler Mining Vehicle

As we all know, crawler vehicles have the following characteristics: large grounding area, stable movement, strong load capacity, strong adaptability of the road surface, and strong obstacle surmounting ability, etc. Scientists and technicians from Germany, France, Russia, South Korea, India, Japan, Belgium, China, and other countries have carried out relevant research on crawler mining vehicles for deep-sea mineral resources mining.

The crawler mining vehicle is powered by the sea surface mining ship through armored cable and operated remotely by the surface operators. The mining vehicle has two or more independent running tracks, each of which is driven by a

Underwater Mining System, Fig. 6 Self-propelled Archimedes mining vehicle (ISA 2008)

hydraulic motor, and travels on the seabed according to the set operation path. The collector picks up the ore such as polymetallic nodules, polymetallic sulfides, and cobalt-rich crusts covered on the seabed. The collected ore can be broken into 10–50 mm particles by the crusher on the mining vehicle according to the design needs, and then sent to the lifting pipe through a flexible hose. The mining vehicle is generally composed of a traveling mechanism, collector, crushing mechanism, hydraulic power system, landing balance device, buoyancy body, electrical and monitoring subsystem, navigation, positioning system, etc.

Self-Propelled Crawler Mining Vehicle for Seabed Polymetallic Nodules

In the seabed polymetallic nodule mining area, the water content of the surface sediments is too high.

The shear strength and bearing strength of surface sediments are exceedingly small, so it is difficult to support the operation of mining vehicles. It puts forward higher requirements for mining vehicles to collect polymetallic nodules from the soft surface sediment to minimize disturbance to the ocean floor to the greatest extent.

Researchers from China, India, South Korea, Belgium, and other countries have carried out the dynamic calculation and virtual prototype design of the mining vehicle, developed the principle prototype of the mining vehicle, and carried out the corresponding principle test. On this basis, a certain scale of commercial mining vehicles has been completed, and the mining vehicles have been carried out mining tests. Up to now, the deep-sea mining test of whole subsystems contained a self-propelled crawler mining vehicle subsystem, and other subsystems such as rise

Underwater Mining System, Fig. 7 China's Self-propelled crawler mining vehicle. (a) Hydro-mechanical combined mining model machine (Jian and Wang 1998).

(b) Prototype of the mining vehicle (Wang 2015). (c) 500-meter sea trial mining vehicle (COMRA 2018)

transportation subsystems have not been carried out.

From 1991 to 1995, two types of hydraulic and hydro-mechanical combined mining model machines were developed in China. From 1996 to 2000, in-situ testing of the geo-mechanical properties of seabed sediments, traction test research of walking mechanism, and driving dynamics research of crawler vehicles was studied, and a prototype of the mining vehicle was developed. The mining test was completed at the depth of 135 m in Fuxian Lake located in Yunnan Province, China in September 2001. Subsequently, the improved design of the miner was completed in 2005. A mining vehicle test pool with a length of 60 m, a width of 50 m, and a depth of 5 m were established in 2006 and the improved mining vehicle was tested in the pool in 2007. Then, another mining vehicle was developed from 2010 to 2017 and was completed a 500-m sea test in the South China Sea in 2018.

The developed self-propelled crawler mining vehicle developed by China (Xie 1995; Jian and Wang 1998), India (Nidhi 2015; Masuda et al. 2014), South Korea (Lee et al. 2013; Sup et al. 2016) and Belgium (GSR 2019) are shown in Figs. 7, 8, 9, and 10.

Self-Propelled Crawler Mining Vehicle for Seabed Cobalt-Rich Crust

As for the mining of seabed polymetallic sulfides, the design of mining vehicles for seabed cobalt-rich crusts can also draw lessons from the mining technology of open-pit mines on land.

With the support of the 12th China Ocean Project, a cobalt-rich crust mining test vehicle was developed for sampling by adopting open-pit continuous mining technology and simultaneously mining and collecting. As shown in Fig. 11, the vehicle mainly consists of a four-track walking mechanism that is independently suspended and driven, an acoustic thickness probe, spiral drum, slurry pump, and other auxiliary devices. When it works, the acoustic thickness probe obtains the thickness of the ore body on the line, the spiral drum is controlled to excavate and crush the crusts according to the obtained thickness of cobalt-rich crust, and the broken crust

particles are collected into the sampler by the slurry pump. In 2018, the sampling test was completed at the depth of 2019 meter in the cobalt crust contract area of COMRA in the Pacific Ocean and a total of 150 kg of crust samples were collected in four tests (CIMR 2018).

Welding methodology

Definition

Underwater welding, just as the name implies, is a specific welding process that is performed while

the welder is submerged in the underwater environment, often at elevated barometric pressures.

Introduction

Welding technology is a powerful fabrication technology that joins materials by employing highly concentrated power energy to melt the components. This technology is widely employed in onshore and offshore structure constructions due to the high productivity during the assembly procedures (Smith and Smith 2009; Fu et al. 2014, 2016). Typically, two stages are included in the welding process, the heating and the cooling stages. Firstly, during the heating stage, the base material is melted, and the melted filler material is deposited simultaneously to the joint. In the heating stage, the melted base and deposited materials form a pool of molten material (molten pool), as shown in Fig. 1. Due to the reduction of power energy input in the cooling stage, the temperature of the molten pool decreased significantly. Finally, the melted base material and deposited filler is cooled to join the construction. Usually, the resistance of the welded configuration (butted joint, full penetration, fillet joint, etc.) is higher than the base material (parent metal).

In some specific working environment, the welding technique is also an efficient way to join the structures (Jeffus 1997). The underwater welding is a common technique to repair the underwater structures in the ships and offshore structure constructions industry, as shown in Fig. 2. Underwater welding, just as the name implies, is a specific welding process that is performed while the welder is submerged in the underwater environment, often at elevated barometric pressures. However, due to the limitation of the in-field working conditions, such as the existence of the electrically conductive medium (water) and the lack of the welding protection, the underwater welding is different from the open-air welding process, and some specific techniques are commonly employed to promote the underwater welding application. For instance, in the offshore platform modules assembly and structure repairing, shielded metal arc welding (SMAW) is

Underwater Welding,**Fig. 1** Molten pool region after the welding (Fu et al. 2014)**Underwater Welding,****Fig. 2** Underwater wet welding process

the popular fabrication process (Muransky et al. 2012; Jeffus 2002; Caprace et al. 2017). However, in controlled environments, specifically for the underwater condition, employing inert gases technique to shield the weld cannot be readily adopted in some situations, due to the unpredictable situation which can result in a poor weld.

Welding Methodology

With the development of the industry construction, a number of welding methods are developed, such as the manual welding methods including shielded metal arc welding (SMAW) and semiautomatic and automatic processes that are the most popular welding technique, such as gas metal arc welding (GMAW), submerged arc welding (SAW), gas tungsten arc welding (GTAW), and flux-cored arc welding (FCAW).

The SMAW, also known as manual metal arc (MMA) welding, or electric welding, is a manual welding technology that employs a welding electrode to weld metals together (Jeffus 1997). Different from the open-air welding, the direct current generated by the energy supply is employed to form the welding arc between the electrode and the workpiece metals in the underwater welding process. Because of the simplicity of application of the welding process, the SMAW is one of the most popular welding processes in the steel structural construction (Fig. 3).

The GMAW commonly termed by its welding technique subtypes, MIG (metal inert gas) welding and MAG (metal active gas) welding, is the welding technique in which a welding arc is generated between the consumable welding electrode and the base metals to be joined, which melts the welding wire and workpiece metal, joining them together (Muransky et al. 2012). With

Underwater Welding,**Fig. 3** The diagram of gas metal arc welding (GMAW) and weld area**Underwater Welding,****Fig. 4** The gas metal arc welding (GMAW) and welding zone

the continuous feeding of the welding wire, a shield gas feeds through a welding gun to protect the welding arc and molten pool from the atmospheric contamination. In the MIG welding process, the inert gas, for instance, argon-based shielding gas or a mix of argon and CO_2 , is employed to protect the welding from the contaminants in the air. However, the active welding gas such as 75% argon and 25% CO_2 is adopted as the shield gas to protect the welding arc and molten pool in MAG welding process. The GMAW welding process is acceptable for most materials and filler wires, and it's one of the most popular welding techniques because of its high productivity and ease of implement to robotic automation (Fig. 4).

The SAW is a common automatically and continuously fed welding wire and a blanket of

granular fusible flux. The welding arc and molten pool are shielded from the contamination in the air by the submerged flux blanket consisting of lime silica, manganese oxide, calcium fluoride, and other components. When the blanket is molten, the flux becomes conductive and provides a current path between the welding wire and base metal. This existence of solid layer of flux covers the weld zone completely, thus preventing spatter and sparks as well as suppressing the intense ultraviolet radiation and fumes (Fig. 5).

The GTAW, known as TIG (tungsten inert gas) welding, employs a nonconsumable tungsten welding wire to perform the welding. The welding arc and molten pool are shielded from the atmospheric contamination and oxidation by the continuously injected inert shielding gas, and a filler metal is usually needed to melt and join the

Underwater Welding, Fig. 5 The diagram of submerged arc welding (SAW) process

Underwater Welding, Fig. 6 The gas tungsten arc welding (GTAW)

structure. The GTAW is usually employed to fabricate the thin stainless steel structures and the nonferrous alloys such as aluminum. Comparing with the other welding technique, the GTAW is relatively complex and difficult to perform, and it is slower than most other welding process (Fig. 6).

The FCAW is commonly identified as MIG while it employs a special tubular electrode filled with powder materials. Usually, this cored electrode is more expensive than the normal solid electrode and can produce slag and fumes during

the welding process. The FCAW can be performed with or without using the shield gas, depending on the filler (Fig. 7).

Recently, with the development of the high concentrated energy equipment, the laser technology, the electron beam welding, beam welding, and magnetic pulse welding have been used widely in the structural construction. Moreover, the solid-state welding processes such as friction welding in which the base metal does not melt have been developed recently.

Underwater Welding Methodology

The welding technique described in the previous section is the common welding technology used widely in the steel construction industry. Moreover, the above described welding technique can be used for the underwater welding process. However, different from the ordinary welding process, in the underwater welding process, the arc is similar to submerged arc welding in underwater combustion and burned in the generated bubbles. When the welding electrode is burned, the coating surrounding the electrode generates a sleeve to stabilize the bubble. In order to make the welding

Underwater Welding, Fig. 7 The flux-cored arc welding (FCAW)

Underwater Welding, Fig. 8 The underwater welding diagram

electrode burn stably underwater, it is necessary to apply a certain thickness of the coating on the electrode core and impregnate it with paraffin or other waterproof material. Bubbles are composed of hydrogen, oxygen, water vapor, and the bubbles generated by the electrode burning and other oxides of turbid smoke. In order to overcome the difficulty of arc stabilization caused by water pressure and the lower temperature, the arcing voltage is higher than the one in the open-air welding process, and the current is 15–20% larger than the welding current in the ordinary welding process.

Normally, the underwater welding can be performed by three methods: wet welding, dry welding, and local dry welding. For wet welding,

usually the divers are entailed in the water to perform the weld directly, as shown in Fig. 2, with the help of the specific equipment. The basic aim of that specific equipment is to protect the diver safety. Usually, it involves using a specially fabricated welding rod and employs a similar process used in ordinary welding, as shown in Fig. 8. For instance, the SMAW is usually adopted for underwater welding in the offshore platforms construction and subsea pipeline repairing. The FCAW and TIG are also common for the underwater welding application.

The second method of underwater welding is dry welding or hyperbaric welding, as shown in Fig. 9. The dry welding is the process by which a chamber is sealed around the weld piece that is to

Underwater Welding,

Fig. 9 The underwater welding with a hyperbaric chamber

be welded. The chamber is then filled with a mixture of helium and oxygen, or argon gas, which then expels the water outside of the chamber and creates a cavity. This allows for a dry environment in which to perform the weld. In the specific designed hyperbaric chamber, the TIG, MIG, FCAW, and SMAW can be conveniently performed. Usually, it has two typical dry welding techniques, high-pressure dry welding and normal-pressure dry welding. For the high-pressure dry welding, the inner pressure of the chamber is higher than the pressure in the welding location; moreover, the inner pressure of the chamber is increased with increase of welding location water depth to expel the water. Usually, the manual metal arc welding and the flux-shielded arc welding are employed. For the normal-pressure dry welding, the inner pressure of the chamber is maintained as the atmospheric pressure. The welding process will not be influenced by the water depth. However, the chamber configuration for the normal-pressure dry welding is more complex in order to maintain the constant inner pressure (1 atm).

Similar to the wet welding, underwater local dry welding entails the diver preforms the welding in the water directly. Normally, a specific designed cover is employed to prevent the water into the weld zone. The gas is injected into the cover to separate the welding arc from the surrounding water. The welding process can be performed in the relatively dry environment. Usually, there are three types of dry welding technique, dry welding technique with large-scaled cover, dry welding method with medium-scaled cover, and dry welding process with small-scaled cover. In the

dry welding process with large-scaled cover, the welding is performed conveniently in a relatively large cavity, and the water was expelled out. In the dry welding process with medium-scaled cover, a special designed cover is employed, and the weld wire is conveniently inserted from a pre-designed channel. The welding process can be performed after the water is expelled by the inner rotating airflow. During the welding process, the gas generated by the welding will be expelled synchronously. In the third underwater local dry welding technology, as shown in Fig. 10, a small cover is composed together with the welding torch. The welding shield gas can separate water from the welding location. During the welding process, the local cavity can move with the welding torch to protect the welding arc.

Summary

The underwater environment makes the welding much more complicated than the open-air welding process. In addition, the underwater welding also involves many factors such as diving operation technology. Usually, the continuous welding procedure is hard to perform due to the limitation of the underwater condition. Normally, the section of welding process is employed and that will induce the discontinuities of the welding. Except that, some other characteristics of the underwater welding can be summarized.

Since the effect of light underwater reflection, absorption, and refraction is much stronger than that of air, the welding visibility is worse in the underwater condition. Moreover, a large amount

Underwater Welding,**Fig. 10** Underwater local dry welding process

of air bubbles and smoke are induced around the welding arc, and the visibility of the welding arc is even worse in underwater condition. The underwater arc will cause thermal decomposition of the surrounding water, resulting in an increase in hydrogen dissolved in the weld. The poor quality of the welded joint is strongly dependent on the hydrogen content generated during the underwater welding.

Since the heat transfer coefficient of water is high, which is about 20 times that of air, the cooling rate is high in the underwater welding process. When the workpiece is to be welded directly in the water, the cold-water quenching effect on the weld is obvious, and it is easy to produce a hardened structure with high embrittlement.

Definition

Very Large Floating Structures (VLFS) constitute a unique concept of ocean structures because of their unprecedented length (on the kilometer

scale), displacement (millions of tons), and nearly billion-dollar predicted cost (Suzuki et al. 2006).

VLFS also have the following characteristics:

1. Hydroelastic response in structural design (Cui et al. 2000).
2. Modular configuration with connectors
3. Use under inhomogeneous environmental sea conditions (Wu et al. 2013).
4. Long design life: 50 ~ 100 years
5. Deployed semipermanently or permanently with complex station-keeping systems

Scientific Fundamentals

Historical Development

The idea of the Very Large Floating Structures (VLFS) first appeared in the modern world in the form of the floating island, which was described in the nineteenth century by the French novelist Jules Verne (Lamasparto et al. 2015). The first to be promoted in serious terms was in circa 1920, when the American Edward R. Armstrong proposed a sea station to be used as an “aeroplane supply and navigating station” (McAllister 1997). Although this proposal was rejected, Armstrong’s early idea that incorporated the principle of a small waterplane area and column-supported platform to minimize motion has been commonly used currently in the design of semisubmersible mobile offshore drilling equipment. Until the period of the Second World War, the US Navy

constructed a miniature floating airport measuring $552 \text{ m} \times 83 \text{ m} \times 1.5 \text{ m}$ with a draft of 0.5 m (Cui et al. 2007).

In recent decades, studies of VLFS were carried out in two major projects. One is the Mega-Float project of Japan. The other one is the Mobile Offshore Base (MOB) project of the USA. In addition, four international conferences on VLFS have been held in the USA and Japan (VLFS 1991, 1996, 1999, 2003). In 2006, the International Ship Structure Conference (ISSC) conducted a comparative study on the hydroelastic response of VLFS (Wu et al. 2017).

In Japan, due to the limited availability of civil land and frequent earthquakes, the Mega-Float project conducted by the Technological Research Association of Mega-Float (TRAM), was established in 1995. The Mega-Float project was divided into two phases. In phase I, from 1995 to 1997, a large floating experimental model 300 m long, 60 m wide, and 2 m deep was built to test the practical issues such as basic design, construction, and technical methods of a Mega-Float, as shown in Fig. 1a. Phase II, which began in 1998, was mainly to examine application technologies required to support the Mega-Float-type airport. In addition, TRAM built a model 1000 m long, 60 m wide (partially 120 m), and 3 m deep in Yokosuka to experiment with landing and takeoff of small airplanes (Suzuki et al. 2006), as shown in Fig. 1b.

MOB is a multifunctional floating comprehensive military base that can be placed in coastal or

Very Large Floating Structures (VLFS): Overview, Fig. 1 Two Mega-Float experimental models (Suzuki et al. 2006)

Very Large Floating Structures (VLFS): Overview, Fig. 2 Mobile Offshore Base Concepts (Suzuki et al. 2006)

international seas and is assembled/disassembled at sea by several self-propelled semisubmersible structural modules, as depicted in Fig. 2. With the MOB concept, the USA could have a base anywhere in the world within 1 month (Lamasparto et al. 2015). In the USA, the first engineering project similar to the MOB was sponsored by the Defense Advanced Research Program Agency (DARPA) with a budget of \$40 M in the early 1990s (McCallister 1997). The Office of Naval Research (ONR) continued to fund the MOB program from 1997 to 2000.

To date, the world's major coastal countries have engaged in the research of VLFS. To develop the fishing and tourism resources near the coral reefs, and to assume the function of wave absorption and island protection, China has funded some research projects on VLFS (Cui et al. 2000; Wu et al. 2013) (see Fig. 3). Because the water depth

in fjords is so great, nearly 500 ~ 1500 m, the Norwegian Public Roads Administration (NPRA) is planning to build several floating bridges/submerged floating tunnels for crossing the fjords on the E39 (Xiang et al. 2016), as shown in Fig. 4. South Korea has also initiated several VLFS projects, such as three floating islands on the Han River and a floating cruise terminal for Seoul (Wang and Tay 2011).

Types of VLFS

VLFS can be generally classified as either pontoon-type or semisubmersible type according to their structure type (Wang and Tay 2011). Pontoon-type VLFS have lesser construction and maintenance costs, while the semisubmersible structures have better wave damping capability (Cui et al. 2000). Figure 5 shows a schematic representation of the two types of VLFS.

Very Large Floating Structures (VLFS): Overview, Fig. 3 VLFS in the South China Sea (Wu et al. 2017; Kou 2011)

Very Large Floating Structures (VLFS): Overview, Fig. 4 VLFS in Norway (<https://www.vegvesen.no/en/home>)

Very Large Floating Structures (VLFS): Overview, Fig. 5 Typical geometry types of VLFS (Cui et al. 2007)

(I) Semisubmersible Type

Generally, the semisubmersible-type VLFS have a raised platform above sea level using columnar tubes. There are mainly two types of semisubmersible VLFS proposed (Cui et al. 2007). One

type has pontoons supported on columns of large diameter and small depth (the column footing type). The other type has pontoons supported by the column and lower hull, whose shape is obtained by extending the present semisubmersible rigs with two lower hulls (the lower hull type).

Semisubmersible VLFS are more suitable for deployment in high seas with large waves and can be stationed in coastal or international waters.

(II) Pontoon Type

Pontoon-type VLFS are also known in the literature as either Box Type or Mat-like because of their box shape and small draft in relation to the length. The pontoon-type VLFS platform rests on the water surface and is intended for deployment in calm waters such as in a cove, a lagoon, or a harbor (Wang and Tay 2011).

Key Technologies

From the investigations of Mega-Float and MOB, the key technical problems involved in the development of VLFS can be summarized in six aspects.

Inhomogeneous Environments

With their relatively small size, the traditional marine structures are generally assumed to be under homogeneous environments. However, for VLFS with several kilometers of length, the sea environments at both ends of the head and tail may be quite different. The differences may include (1) wave conditions; (2) current conditions; (3) wind conditions; and (4) nonuniform topography (Cui et al. 2007). Moreover, the VLFS is usually deployed in nearshore seas with varying water depths (Utsunomiya et al. 2001), offshore seas sheltered by breakwaters (Nagata et al. 1998), or fjords/islands with complex topography (Wei et al. 2019; Wu et al. 2013). In addition, the ocean waves can be easily affected by islands, breakwaters, or the shores of fjords/islands when propagating from the open sea with certain angles, and the wavefield will then become inhomogeneous. These inhomogeneous environments can lead to large loads for the connectors, mooring systems, and other components of the VLFS.

Hydroelastic Response

Distinguished from traditional marine structures by their large size and relatively low structural stiffness, VLFS exhibit responses in waves that

include rigid body motions and obvious structural deformations. Because of the strong coupling between structural deformations and fluid motions, the responses of VLFS should be determined by hydroelasticity theories. Hydroelastic responses are the main causes of the structure and connector failure such as buckling and fatigue. Thus, the accurate prediction of the hydroelastic responses of a VLFS is a prerequisite for a safe and economic design. In the last several decades, frequency domain hydroelasticity theories have been developed from 2D (Bishop and Price 1979) to 3D (Wu 1984), from linear (Wu and Wang 1993) to nonlinear theories (Chen et al. 2003b), and applied to estimate hydroelastic responses of VLFS. However, the studies of hydroelasticity analysis of VLFS have been mainly restricted to homogeneous waves. When the oceanic environment around the VLFS is inhomogeneous, the traditional hydroelasticity theory based on homogeneous waves is no longer applicable. Even so, the studies of hydroelastic responses under inhomogeneous sea environments are still relatively few (Wu et al. 2013, 2017).

Station-Keeping Systems for VLFS

The station-keeping system ensures that the VLFS is kept in position so that the facilities installed on the structure can be reliably operated and to prevent the structure from drifting away under critical sea environments (Wang and Tay 2011). Similar to traditional marine structures, the station-keeping systems for VLFS can be grouped into three main types: (1) the dolphin fender mooring system, (2) the mooring line system, and (3) the dynamic positioning system. In shallow water area, a dolphin fender mooring system is the most reliable, albeit expensive. Catenary chain mooring is available even in shallow water if a midpoint sinker or buoy is used. If the water depth is over 500 m, compliant type mooring, taut mooring, or dynamic positioning systems are preferable to the catenary mooring system (Cui et al. 2007). Due to the massive size of the VLFS, the station-keeping system design and analysis have become more complex.

Connectors for VLFS

The massive continuum structure of a VLFS is usually divided into several separate modules.

The modules are fabricated in the shipyard and then connected on-site in the open sea by welding or using connectors. For multimodular floating systems, the connector between modules becomes the weakest component in the whole system, which means it is subjected to large loads and easily damaged. For thousand-meter-scale floating systems, the connection load may exceed 10,000 t in the sixth sea state (Riggs et al. 2000). Various connector designs have been proposed for VLFS, including rigid or hinge connectors (Maeda et al. 1979), semirigid connectors (Fu et al. 2007), flexible connectors (Wu et al. 2016), and other compliant connectors (Xia et al. 2016). However, the strength and economic issues of the connectors have still been a long-standing technical bottleneck for developing multimodular floating systems.

Structural Analysis and Design of VLFS

The purpose of structural design is to develop a structure that can satisfy the maintainability and safety requirements in an economic manner. For innovative structures such as VLFS, structural design needs to be based on reasonable structural response analysis and explicit design criteria (Suzuki et al. 2006). However, there is no complete specification or standard to follow during the design of VLFS. It is mainly designed according to functional requirements, and then the safety of the structure is evaluated by direct numerical calculation or model test methods. The safety design limit states for VLFS include the ultimate limit state (ULS), the fatigue limit state (FLS), the serviceability limit state (SLS), and the progressive collapse limit state (PLS) (Fujikubo 2005). The manner of establishing the corresponding design criteria and procedures has always been the focus of scholarly research (Cui et al. 2000).

Experimental Techniques for VLFS

The development of any new theory/method is inseparable from its experimental verification. The two main approaches to carrying out experimental research are full-scale measurement and model tests. Compared with full-scale measurements, model tests of VLFS are more practical and economical (Cui et al. 2007). Though model tests of a VLFS are very important, there are several

peculiar problems in model experiments. To conduct model experiments in wave basins, it is necessary to reduce the scale of the very large

Very Large Floating Structures (VLFS): Overview, Fig. 6 Floating Pier at Ujina, Japan (Watanabe et al. 2004)

Very Large Floating Structures (VLFS): Overview, Fig. 7 Kamigoto floating oil storage base, Japan (Wang and Tay 2011)

(kilometer scale) prototype to an extraordinarily small scale. This may cause a problem in the wave simulation capability of wave basins and the accuracy of measuring the behavior of the model. Moreover, the simulation of inhomogeneous sea environments is also a great challenge to wave-making technology in wave basins. In short, the characteristics of VLFS greatly increase the difficulty of model tests, and it is quite necessary to carry out further research (Chen et al. 2003a).

Very Large Floating Structures (VLFS): Overview, Fig. 9 Seoul Floating Islands, South Korea (www.archdaily.com)

Key Applications

VLFS are designed primarily for floating airports (see Fig. 1), floating military bases (see Fig. 2), and floating bridges (see Fig. 4). However, VLFS could be used for a variety of purposes.

Floating Ports

Floating structures are ideal choice for ports, because the ships can come alongside them since their positions are constant with respect to the waterline (Watanabe et al. 2004). Moreover, the floating ports may also be beneficial in siting offshore termini for potentially hazardous vessels, such as LNG carriers (Suzuki et al. 2006). An example of a floating port is Ujina Port at Hiroshima, which was built by Japan in 1993 (see Fig. 6).

Energy Storage

Another important use of VLFS is the development of facilities for fuel storage. The Kamigoto Oil Storage Base is a facility of 5 units of $390 \times 97 \times 27.6$ m, which is one of the nation's ten national oil stockpile bases, for which see Fig. 7 (Suzuki et al. 2006; Wang and Tay 2011). This floating oil storage is equipped to store different kinds of oil, such as gasoline, domestic fuel, and jet fuel.

Very Large Floating Structures (VLFS): Overview, Fig. 10 Floating city, Japan (www.wordlesstech.com)

Very Large Floating Structures (VLFS): Overview, Fig. 11 Floating city, Belgium (www.vincent.callebaut.org)

Recreation and Residential Areas

VLFS could be constructed as recreation and residential facilities, including restaurants, hotels, and performance stages. Singapore has built the world's largest floating performance stage. It is 120 m long, 83 m wide, and 1.2 m deep, as shown in Fig. 8, and is located at Marina Bay. With convention halls, restaurants, and other tourist attractions, the Seoul Floating Islands have been built by South Korea, as shown in Fig. 9.

Floating Cities

With the development of VLFS technologies, it is possible that large human habitation and floating cities will be built on the ocean surface in the future. These facilities can either be fixed to coastal cities or free-floating in international waters. A design concept of the future water city proposed by Japan's Shimizu Technology Corporation (see Fig. 10), focusing on the use of green science concepts to build a carbon-neutral city, is planned to be completed in 2025. The famous Belgian architectural designer Vincent Callebaut proposed the "Lily Petal" water mobile city model, which is a floating amphibious city that can float on the earth according to different wind directions and climates, as shown in Fig. 11.

Vortex Shedding and VIV Suppression

Wanhai Xu

State Key Laboratory of Hydraulic Engineering Simulation and Safety, Tianjin University, Tianjin, China

Introduction

Vortex-induced vibration (VIV) is a fluid-structure interaction (FSI) phenomenon in which the structure is excited into vibration under the forces induced by the vortices alternatively shed from the surface of a bluff body. VIV is a major concern which has the potential to cause the fatigue failure of the structures in many engineering applications. The suppression of VIV minimizes the fatigue effects prolonging the integrity of the structures and avoiding or deferring the

costs associated with replacement or repair of the structures.

Vortex Shedding

Definition of Vortex Shedding

Vortex shedding is the phenomenon in which vortices are shed alternatively at either side of a bluff body at a certain frequency, and consequently the wake has an appearance of a vortex street as illustrated in Fig. 1.

Mechanism of Vortex Shedding

Flows past bluff bodies with different cross-sectional shapes, to some extent, share similar characteristics. Herein, the flow features around a circular cylinder are taken as an example due to the facts that the key structural components in offshore engineering are usually of a cylindrical shape and the flow past a circular cylinder has been extensively studied in the literature.

When a fluid particle flows toward the leading edge of a circular cylinder, the pressure in the fluid particle experiences a rise from the freestream pressure to the stagnation pressure. The high fluid pressure near the leading edge impels the developing boundary layers about both sides of the cylinder. However, the pressure forces are not sufficient enough to force the boundary layers around the back side of the cylinder at certain

flow velocities. Near the widest section of the cylinder, the boundary layers separate from each side of the cylinder surface and form two free shear layers which trail aft in the flow and bound the wake. Since the innermost portion of the free shear layers moves much more slowly than the outermost portion of the layers, which are in contact with the free stream, the free shear layers tend to roll up into two discrete swirling vortices. The pair formed by these two vortices is actually unstable when exposed to small disturbances for Reynolds numbers $Re = \frac{UD}{\nu} > 40$, where U is the freestream velocity, D is the diameter of the cylinder, and ν is the kinematic viscosity of the fluid. Consequently, one vortex will grow larger than the other if $Re > 40$. The larger vortex (Vortex A in Fig. 2a) presumably becomes strong enough to draw the opposing vortex (Vortex B) across the wake, as sketched in Fig. 2a. The vorticity in Vortex A is in the clockwise direction, while that in Vortex B is in the counterclockwise direction. The approach of vorticity of the opposite sign will then cut off further supply of vorticity to Vortex A from its boundary layer. This is the instant where Vortex A is shed. Vortex A is then convected downstream by the flow once it becomes a free vortex.

Following the shedding of Vortex A, a new vortex will be formed at the same side of the cylinder, namely, Vortex C (Fig. 2b). Vortex B will now play the same role as Vortex A, namely, it will grow in size and strength so that

Vortex Shedding and VIV Suppression,

Fig. 1 Appearance of vortex shedding behind a circular cylinder in a stream of oil at $Re = 161$ (Homann 1936)

Vortex Shedding and VIV Suppression,

Fig. 2 Mechanism of vortex shedding (Sumer and Fredsøe 2006)

it will draw Vortex C across the wake (Fig. 2b). This will lead to the shedding of Vortex B. This process will continue each time a new vortex is shed at one side of the cylinder where the shedding will continue to occur in an alternative manner between the sides of the cylinder.

Flow Regimes Around a Circular Cylinder

The flow around the cylinder can be classified into different regimes as Re is increased from zero. Figure 3 presents different flow regimes around a smooth circular cylinder as summarized in Sumer and Fredsøe (2006).

a		No separation. Creeping flow	$Re < 5$
b		A fixed pair of symmetric vortices	$5 < Re < 40$
c		Laminar vortex street	$40 < Re < 200$
d		Transition to turbulence in the wake	$200 < Re < 300$
e		Wake completely turbulent. A: Laminar boundary layer separation	$300 < Re < 3 \times 10^5$ Subcritical
f		A: Laminar boundary layer separation B: Turbulent boundary layer separation; but boundary layer laminar	$3 \times 10^5 < Re < 3.5 \times 10^5$ Critical {Lower transition}
g		B: Turbulent boundary layer separation; the boundary layer partly laminar partly turbulent	$3.5 \times 10^5 < Re < 1.5 \times 10^6$ Supercritical
h		C: Boundary layer com- pletely turbulent at one side	$1.5 \times 10^6 < Re < 4 \times 10^6$ Upper transition
i		C: Boundary layer com- pletely turbulent at two sides	$4 \times 10^6 < Re$ Transcritical

Vortex Shedding and VIV Suppression, Fig. 3 Regimes of flow around a smooth circular cylinder (Sumer and Fredsøe 2006)

When $Re < 5$, the flow attaches to the cylinder surface and no separation occurs. With the increase in Re , due to the adverse gradients imposed by the divergent geometry of the flow environment, the boundary layers separate from each side of the cylinder surface becoming two free shear layers in the wake. Flow separation as sketched in Fig. 4 first appears when Re becomes 5. For the range of $5 < Re < 40$, a pair of symmetric vortices forms in the wake of the cylinder. The vortex formation length increases with increasing Re (Batchelor 1967). When Re is further increased, the wake becomes unstable, which would eventually give birth to the vortex shedding phenomenon.

Vortex Shedding Frequency

The frequency at which the alternative vortices are shed, f_s , can be normalized with the flow velocity U and the cylinder diameter D to form the so-called Strouhal number.

Vortex Shedding and VIV Suppression, Fig. 4 A sketch of flow separation (Sumer and Fredsøe 2006)

$$St = \frac{f_s D}{U}$$

Since the flow around a circular cylinder is governed by Re , St can on dimensional grounds be seen to be a function of Re . Figure 5 presents the variation of St with Re . The report of St starts from $Re = 40$. For $40 < Re < 200$, the vortex street is laminar, and the vortex shedding is essentially 2D. In this range, St increases linearly with Re . The transition in the wake region occurs when $200 < Re < 300$. Two discontinuities are observed in St in the experimental data by Williamson (1992). The dislocation of the vortices leads to the first discontinuity as the flow changes from 2D to Mode A (see Fig. 6a). The second discontinuity occurs as the flow transits from Mode A to Mode B as shown in Fig. 6b. In the Re range of $300 < Re < 3 \times 10^5$, the wake is completely turbulent, whereas the boundary layer over the cylinder surface remains laminar. This regime is known as the subcritical flow regime where St is almost constant at $St \approx 0.2$. With a further increase in Re , the flow enters the critical regime ($3 \times 10^5 < Re < 3.5 \times 10^5$). In the critical regime, the boundary layer separation is turbulent on one side of the cylinder and laminar on the other side. The next flow regime is the supercritical regime where $3.5 \times 10^5 < Re < 1.5 \times 10^6$. In this regime, the boundary layer on both sides of the cylinder is turbulent at the separation points. This results in a

Vortex Shedding and VIV Suppression,

Fig. 5 Variation of the Strouhal number with the Reynolds number for a smooth cylinder (Williamson 1989; Roshko 1961; Schewe 1983)

Vortex Shedding and VIV Suppression, Fig. 6 Mode A and B three-dimensional vortex shedding. (a) Mode A represents the inception of streamwise vortex loops,

and (b) Mode B represents the formation of finer-scale streamwise vortex pairs (Williamson 1992)

delay in the boundary layer separation where the separation points move downstream. This means the vortices would interact at a faster rate. Therefore, a dramatic increase in St from 0.2 to 0.45 is seen in this regime. The Strouhal number experiences another discontinuity when Re reaches the value of 1.5×10^6 . At this Re , transition to turbulence in one of the boundary layers has been completed (Fig. 3h). The boundary layer on one side of the cylinder is completely turbulent, and that on the other side is partly laminar and partly turbulent. The asymmetric situation causes the formation of the lee-wake vortices, and it prevails over the whole upper transition regime ($1.5 \times 10^6 < Re < 4 \times 10^6$). The regular vortex shedding is re-established in the transcritical flow regime where St takes the value of 0.25–0.3.

Vortex-Induced Vibration (VIV) Suppression

Vortex-Induced Vibration (VIV) Suppression and Its Principles

As VIV is induced by the alternatively shed vortices, adjusting the locations of the separation

points, varying the fluid forces, and controlling strengths of the vortices in the wake could mitigate the effects of VIV. Vortex-induced resonance rises when the structural vibration frequency is close to the natural frequency of the structure. Therefore, modifying the characteristic length, changing the cross-sectional shape, or adding appendages can effectively avoid the occurrence of vortex-induced resonance.

Modifying Structural Parameters

Figure 7(a) shows the one-degree-of-freedom VIV response of an elastically mounted circular cylinder with a low mass ratio $m^* = 2.4$ (Khalak and Williamson 1997). It can be seen that when the reduced velocity ($V_r = U/f_n D$) is low, the amplitude of the circular cylinder is relatively small, and the oscillation frequency f_y follows the stationary-cylinder Strouhal frequency f_{st} until it approaches the natural frequency of the circular cylinder f_n . From this point on, with a further increase in V_r , f_y deviates from f_{st} , and the ratio of f_y to f_n remains constant. The V_r region in which f_y is close to f_n is referred to as the lock-in range (Williamson and Govardhan 2004). In this

Vortex Shedding and VIV Suppression, Fig. 7 One-degree-of-freedom VIV responses of a circular cylinder: (a) amplitude response and (b) frequency response (Khalak and Williamson 1997)

corresponding range, the cylinder undergoes large-amplitude vibrations. Beyond the lock-in range, the vibration amplitude of the cylinder reduces and f_y returns to f_{st} .

Based on the descriptions above, it can be concluded that the VIV amplitude reaches its maxima when the cylinder is subject to vortex-induced resonance. Therefore, the large-amplitude resonant response of the cylinder under certain incoming flow conditions could be inhibited by modifying the structural parameters. The characteristic length or the natural frequency might be changed to keep away from the lock-in-reduced velocities. In order to suppress VIV of risers or pipelines, the statistics about the flow velocity range of the sea area are a priori. Although the sizes of risers or pipelines are usually restricted by the rules and regulations, their characteristics lengths could be modified by adding insulations. Varying the natural frequencies of risers or pipelines can be achieved by changing their masses, lengths, bending stiffness, and/or tensions (if applicable).

Adjusting Boundary Layer Separation Point Locations

The locations of the boundary layer separation points are related to the cross-sectional shape, the surface roughness, and the Reynolds number. For bluff bodies with sharp corners (e.g., a square cylinder), the separation points are usually at the

corners. The cross-sectional shape has to be changed in order to change the separation point locations.

Figure 8 demonstrates three modifications to the cross-sectional shapes which could adjust the locations of boundary layer separation points. By modifying the corners, the reattachment of the separated shear layers is promoted. As a result of the reattachment, the strength of the vortex street is decreased, and the wake width is narrowed (Tamura and Miyagi 1999; Ueda et al. 2009).

For circular cylinders, the boundary layer separation locations can be directly shifted by changing their cross-sectional shapes, for example, installing a fairing on the rear of a cylinder (see Fig. 9). In this way, the bluff circular cylinder is converted to streamlined shape so that the boundary layer separation point locations are modified.

In addition, the locations of the boundary layer separation points might be delayed by injecting momentum into the wake flow. As shown in Fig. 10, a nozzle is installed on the rear side of the cylinder (Feng et al. 2010, 2011; Gao et al. 2019). By pumping extra fluid into the wake as a high-speed jet, the shear layers on both sides of the cylinder move toward the centerline to shift the boundary layer backward.

Suppressing Development of Wake Vortices

The fluid forces acting on the structures are dependent on the formation and convection of the

Vortex Shedding and VIV Suppression, Fig. 8 (a) Square cylinder with round corners, (b) square cylinder with chamfered corners, and (c) square cylinder with cut corners at the front edges

Vortex Shedding and VIV Suppression, Fig. 9 A sketch of flow past a circular cylinder with a sharp-tail fairing

Vortex Shedding and VIV Suppression, Fig. 11 A sketch of flow past a circular cylinder with a splitter plate

Vortex Shedding and VIV Suppression, Fig. 10 A sketch of flow past a circular cylinder with synthetic jet into its wake

vortices. The fluid forces are larger when the vortices are formed, and the magnitudes of the fluid forces decrease as the vortices are convected downstream. Therefore, VIV could also be suppressed by interfering the formation and development of wake vortices.

Splitter plates as shown in Fig. 11 are typical devices used to suppress the development of wake vortices. They separate the wake region into the upper and lower parts so that the separated shear layers do not have enough space to roll up into

large vortices but are forced to break into small vortices or convected along the surfaces of the splitter plates. Furthermore, the presence of splitter plates also modifies the shear layer interaction in the near wake of the cylinder.

Typical VIV Suppression Devices

Helical Strakes

A widely used method for suppressing VIV of long slender bodies of circular cross section is the attachment of helical strakes. As shown in Fig. 12, helical strakes consist of one or more fins that spiral along the span of the structures. The fins cause the vortices along the span to be broken up into shorter and weaker segments. Furthermore, the breaking up of the vortices reduces their ability to correlate along the span resulting in a series of vortices randomly phased in time.

The helical strakes were invented by Christopher Scruton and D. E. J. Walshe at the National Physics Laboratory in the UK (Scruton and Walshe 1957) and have been subsequently employed in the wind engineering since the early 1960s. It was not until the late 1970s that the

Vortex Shedding and VIV Suppression, Fig. 12 Helical strakes

helical strakes were seen on slender marine structures for VIV suppression. The main advantage of helical strakes is that they are less sensitive to the direction of the flow whereas they suffer from two major problems: the first being that they increase drag and the second that for a given strake height, their effectiveness reduces with decreases in the response parameter $m\zeta$. Allen et al. (2006) discovered that helical strakes with a triple-start strake geometry of $0.1D$ high strakes with a $5D$ pitch-per-start can suppress VIV very efficiently at a wide range of Re .

Fairings

A second device for suppression of the VIV of offshore oil and gas tubulars is the fairing. As shown in Fig. 13, fairings consist of a structure having two sides with the aim of streamlining the flow past the structure. The short fairing was pioneered by Allen and Henning (Allen 1989; Allen and Henning 1995), while longer fairings were moderately successful when used on offshore drilling risers in the late 1970s and early 1980s. Allen and Henning (2007) found that short and even ultrashort fairings could be very effective at VIV suppression. Moreover, fairings have lower drag than helical strakes. Khorasanchi and Huang (2014) analyzed the vibration response of a circular cylinder with fairing. As fairings were added to the cylinder, the center of gravity of the system would shift from the cylinder axis, which may lead to the instability problem. Consequently,

Vortex Shedding and VIV Suppression, Fig. 13 Marine riser fitted with fairings

the fairings should be designed in such a way that the center of gravity of the system stays close to the axis of the cylinder. Additionally, the structural damping could be increased to ensure the stability of the system.

Splitter Plates

For helical strakes, sharp-edged separation with its accompanying high drag is required to maintain three-dimensional separation and suppress VIV. At values of $m\zeta$ typical for risers (less than 0.1), it seems that three-dimensional solutions for VIV suppression are unlikely to provide satisfactory effectiveness of VIV suppression with reduced drag. There are a number of two-dimensional control devices to weaken vortex shedding and reduce drag, with the most well-known being the splitter plate. The primary vortex shedding can be suppressed given that the splitter plates are sufficiently long. The experimental data by Huera-Huarte (2014) indicates that it is not necessary to cover the whole risers or pipelines with splitter plates. The splitter plates could be distributed at certain spacings. This kind of arrangement is not only cost saving but also can achieve good VIV suppression effectiveness.

Synonyms

[Deep-sea mining](#); [Deployment and recovery](#);
[Water surface support system](#)

Introduction

The water surface support system is not only a floating platform for seabed mining, slurry lifting and conveying, a control center for seabed mining equipment, and a living place for staff, but also has special functions for dewatering the slurry lifted from the seabed and unloading the ore to the transport barge. It provides space for underwater mining equipment and mineral storage area, and supports water surface distribution and recovery and underwater mining operations (Liu et al. [2015](#)).

Main Components

The distribution and recovery system are mainly composed of the following subsystems:

Layout and recovery system of mining vehicle
Umbilical deployment and recovery system
Pipe connection and dismantling device
Hoisting system
Heave compensation system
Steel tower
Base platform
Pipeline storage transfer and auxiliary connection system
Water surface support cooperative control system
Pipe ship coupling device

Water Surface Support (Layout and Recovery)

System, Fig. 1 Water surface support (layout and recovery) system

Placing transfer device in underwater relay station
Hose placement and recovery system
Pipe clamping device (Fig. 1).

Function

Under the predetermined sea conditions, the reasonable, orderly, safe, and efficient placement and recovery operation of the underwater equipment and facilities involved in the seabed ore gathering and navigation positioning system, underwater transportation system, and power transmission and control system can adapt to the adverse impact caused by the heave and swing motion caused by wind, wave, and current.

Key Application

Under the specified sea conditions, all underwater equipment, such as the submarine ore collection and navigation and positioning system, underwater transport system, power transport, and control system, shall be laid out and recovered in accordance with reasonable and orderly lifting, docking, and releasing processes to support and ensure the smooth operation of seabed mineral collection (Yang et al. 2019).

Important Scientific Issues or Technologies

Heave Compensation Technology for Heavy Haul and Long Stroke

In the process of deep-sea mining, the pipeline transportation system weighing hundreds of tons

and thousands of meters long is suspended under the water surface support platform, and the end of the hard pipe is hundreds of meters away from the seabed. The vertical heave movement of long-distance pipeline transportation system will occur under the induced load of complex marine environment, which will affect the operation safety of surface support platform and the stability of slurry transportation.

Overall Integration Technology of Placement and Recovery

The layout and recovery system needs to complete the layout and recovery of many systems or equipment involved in the seabed ore gathering and navigation positioning system, underwater transportation system, and power transmission and control system under the predetermined sea conditions. There are many objects to be laid out, the interface difference is large, and the operation time is long.

Layout and Recovery System Equipment

Layout and Recovery System of Mining Vehicle

The layout and recovery system of mining vehicle mainly realizes the layout and recovery of mining vehicle from the stern deck to the seabed, the smooth water inflow and outflow of the mining vehicle, the tension compensation in the process of mining vehicle lowering or recovery, and the compensation for ship heave movement during landing or leaving the bottom, so as to ensure the safety of mining vehicle (Fig. 2).

Water Surface Support (Layout and Recovery) System, Fig. 2

The layout and recovery of mining vehicle

Water Surface Support (Layout and Recovery) System, Fig. 3 The umbilical winch

automatic operation of low constant tension in the process of laying or recovering each cable, to ensure the safety of the system (Fig. 3).

Pipe Connection and Dismantling Device

The main function of the pipeline docking and dismantling system is to realize the rapid installation and disassembly of thousands of meters long lifting pipe which needs to be put into water during the process of laying or recycling in deep-sea mining (Fig. 4).

Lifting System

The lifting system mainly realizes the lifting and lowering of laying objects, and also takes into account the centralized operation, data information interaction, and control center involved in the process of pipeline processing (docking or dismantling, lifting, or placing) (Fig. 5).

Umbilical Deployment and Recovery System

The umbilical cable distribution and recovery system can realize the synchronous action of the umbilical cable in the process of laying or recovering the mining vehicle from the stern deck to the seabed, and the synchronous action of the umbilical cable in the process of laying or recovering the underwater equipment from the moon pool to the seabed. At the same time, it can realize the

Heave Compensation System

The heave compensation system can provide vertical support force and heave compensation force for the hard pipe through the up and down movement of the oil cylinder piston rod of the oil cylinder system, to control the stress and displacement of the hard pipe, and keep the tension of the hard pipe basically constant under the condition of the vertical movement of the mining ship, to reduce the risk of fatigue damage and dynamic

Water Surface Support (Layout and Recovery) System, Fig. 4 The casing tongs

Water Surface Support (Layout and Recovery) System, Fig. 5 The lifting system

Water Surface Support (Layout and Recovery) System, Fig. 6 The model of heave compensation system

compression of the underwater transportation pipeline system, and keep the pulp transportation relative to the sea bottom height stable, to improve the overall operation safety (Fig. 6).

Steel Structure Tower and Base Platform

The steel structure tower is mainly used to install the crane of the hoisting system and

Water Surface Support (Layout and Recovery) System, Fig. 7 The steel structure tower and base platform

hang the traveling equipment, and assist in the placement and recovery of the equipment. The base platform provides support for steel structure tower, lifting system, and related equipment, and provides installation position and operation space for equipment operation. In the process of lowering and lifting hard pipe, it is used as temporary suspension bearing body of underwater transportation system, and is also a platform for pipeline butt joint and disassembly (Fig. 7).

Pipeline Storage Transfer and Auxiliary Connection System

The pipeline storage and transfer and auxiliary connection system mainly realizes the safe transfer of the hard pipe and lifting pump between the deck storage area and the base plane in the laying and recycling stage, so as to meet the requirements of laying and recycling operation efficiency, and provide reasonable storage space and storage position for the hard pipe and lifting pump (Figs. 8 and 9).

Water Surface Support (Layout and Recovery) System, Fig. 8 The pipe grabbing crane

Water Surface Support Cooperative Control System

The water surface support cooperative control system mainly realizes the function of relay station and mining vehicle-coordinated lowering. In the process of laying or reclaiming operation, “OPC + Ethernet” mode is used for communication, and the tail winch is controlled to lay the mining vehicle, to ensure that the height difference between the mining vehicle and the deployment relay station of moon pool in the ship is maintained, and to realize the coordinated laying process of the relay station and the mining vehicle. At the same time, the real-time status, parameter information, and alarm information of key equipment are collected, processed, and displayed in the process of placing or recycling (Fig. 10).

Pipe Ship Coupling Device

The pipe ship coupling device is used to compensate the heave displacement and angular displacement of the pipeline caused by waves. Its upper end is connected with the base platform, and the lower end is connected with the slurry pipeline (Fig. 11).

Water Surface Support (Layout and Recovery) System, Fig. 9 The power catwalk

Water Surface Support (Layout and Recovery) System, Fig. 10 The main software interface of the water surface collaborative control system

Placing Transfer Device in Underwater Relay Station

The layout and transfer device of underwater relay station mainly meets the requirements of loading

and transferring of underwater relay station in the process of laying and recycling, realizes the end clamping of hose, and provides operable space for manual docking between underwater relay station

and hose; it also takes into account the platform operation conditions such as umbilical cable connection of underwater relay station, signal beacon

of underwater relay station, heave compensation installation, and other platform operation conditions, which can facilitate other manual auxiliary operation process work around the moon pool (Fig. 12).

Hose Placement and Recovery System

The hose laying and recovery system mainly realizes the arrangement of the head end of the hose from the side of the ship and towing to the stern of the ship to connect with the mining vehicle. In the process of hose laying or recycling, the buoyancy block and beacon are bound, fixed or disassembled, and homing. The end of the towing hose is connected with the underwater relay station through the moon pool (Figs. 13 and 14).

Pipe Clamping Device

As an important bearing part of the water surface support deployment and recovery system, the pipe clamping device is embedded on the working surface of the base platform. In the process of laying and recycling the underwater equipment, the pipe clamping device holds the pipeline to provide support and operation conditions for the pipeline docking and disassembly (Fig. 15).

WEC – Wave energy converter

Definition

Wave energy converter is a device or a plant which is set up to convert wave energy into useful energy, such as electricity, or provide power for other purposes, such as seawater desalination, etc.

Scientific Fundamentals

Generally, a wave energy converter consists of two or three main stages in converting wave energy into useful power. In the primary wave energy conversion, with the interaction of the wave and structure(s), the wave energy can be converted into mechanical/pneumatic/potential energy, depending on the types of wave energy

converter, while in the secondary energy conversion, the power take-offs (PTOs, see power take-off) are used to further convert the trapped energy into useful mechanical energy (and finally into electricity in the tertiary conversion stage using the generators).

Technology Classification

It has been reported that up to date more than 1000 wave energy technologies have been patented (see Falcao 2010), but in reality only a handful wave energy converting technologies have been effectively proven using numerical and/or experimental studies, and some of them have been advanced to higher technology readiness levels (TRLs), and fewer even reach the pre-commercial sea trials in real seas or generate power to the grid.

Classifying all wave energy technologies has been attempted by different researchers, and several different classifications for wave energy technologies have been proposed, and some good examples can be found in (Falcao 2010; Drew et al. 2009; EMEC 2018). In a rather simple form, Falcao (2010) classifies the wave energy technologies into three main types, oscillating water columns, oscillating bodies, and overtopping devices (see Fig. 1), although this classification may not include all the proposed or developed wave energy technologies. However, it uses a rather simple form to cover the main-streams of the wave energy conversion technologies, mainly based on the types of four power take-offs (PTOs), including (1) air turbines for oscillating water columns; (2) hydraulic systems and (3) direct drives for oscillating bodies; and (4) low head water turbines for overtopping devices. It can be also seen that all these three types of wave energy technologies can be further classified as floating and fixed devices or, in more appropriate definitions, fix-referenced and self-referenced devices (Sheng and Lewis 2016).

Mathematical Modelling of Wave Energy Conversion

Generally, both frequency-domain and time-domain analysis methods of hydrodynamics of wave energy converters can be employed for studying the forces acting on and the motions

Wave Energy Converters, Fig. 1 Categories of wave energy converters (Falcao 2010)

of the wave energy devices in waves, and the modelling would be depending on the requirements or the practical problems. Frequency-domain analysis is fast, but it is only used for linear systems, while time-domain analysis is much more time-consuming and can be used in nonlinear systems. Here only the popular frequency-domain and time-domain methods are briefly discussed.

Frequency-Domain Analysis

Frequency-domain analysis is based on the assumptions of the Laplace equation and the linear boundary conditions in the potential flow. To solve such a linear equation, the superimposition principle can be employed which could significantly simplify the dynamic problems. For instance, for the wave-structure interaction problems, the total velocity potential function flow can be decomposed into diffracted and radiated velocity potentials, and these potential components can be solved independently based on the different hydrodynamic boundary conditions:

- Velocity potential for incoming waves and velocity potential for the scattered waves (due

to the existence of the structure in waves): diffraction problem

- Velocity potential for the radiated waves (due to the motions of the structure): radiation problem

The diffracted problem accounts for the interaction of the structure and wave under the assumption that the structure is fixed in the fluid. When the waves interact with the structure, the structure may reflect and refract the waves due to the existence of the structure. The total waves comprising the incoming waves and the reflected/deflected waves are called the diffracted waves. The solution for the diffracted problem is the excitation forces/moments acting on the structure due to the diffracted waves.

The radiated problem accounts for the case in which the structure moves in an oscillating manner in calm fluid. As such, the structure generates waves which radiate away in all directions (in 3D cases). The solution of the radiated problem is the added mass and potential damping forces and moments due to the radiated waves. The restoring forces and moments due to the motions of the structure will also be obtained.

These two independent problems (the diffracted problem and the radiated problem) form the full hydrodynamic problem for the potential flow thanks to the superimposition principle.

To solve the potential flow problems, the boundary element method (BEM) has been developed in the last century, with strict mathematical derivation (see details in books Newman 1977; Faltinsen 1990; Falnes 2002). Now some commercial and open-source BEM are available (WAMIT 2016; AQWA; Parisella and Gourlay 2016) for both research and industry applications.

In frequency domain, the dynamic equation of motions for the wave energy converter is very similar to that of the conventional floating structures in waves but with an additional force from the power take-off system for wave energy conversion. The generalized frequency-domain dynamic equation for the wave energy converters is given as

$$\{-\omega^2[\mathbf{M} + \mathbf{a}(\omega)] + i\omega \mathbf{b}(\omega) + \mathbf{C}\} \mathbf{x}(\omega) = \mathbf{f}_{\text{ex}}(\omega) + \mathbf{f}_{\text{pto}} + \mathbf{f}_{\text{mooring}} \quad (1)$$

where $\mathbf{M}$ is the mass matrix of the wave energy converter; $\mathbf{C}$ the restoring force coefficient matrix; $\mathbf{a}$ and $\mathbf{b}$ the added mass and the damping coefficient matrix (from the solution of the radiated problem); $\mathbf{x}$ the complex amplitude vector of the motions; $\mathbf{f}_{\text{ex}}$ the excitation vector; $\mathbf{f}_{\text{pto}}$ the power take-off force vector; and $\mathbf{f}_{\text{mooring}}$ the linear or linearized mooring force vector.

The average converted power is calculated as

$$\bar{P}_{\text{reg}} = \frac{1}{2} \omega \text{Re} (\mathbf{f}_{\text{pto}} \cdot \mathbf{x}^*) \quad (2)$$

where the superscript $*$ means a conjugate of the complex vector.

When the motion in Eq. (2) is given as the response (the motion in the wave of a unit amplitude) as the conventional outputs from the BEM software, $\bar{P}_{\text{reg}}$ can be considered as the power response curve (the wave energy conversion in the wave of unit amplitude). Then in irregular waves, the capture power for a given spectrum $S(\omega)$ can be calculated as

$$\bar{P}_{\text{irr}} = 2 \int_0^\infty \bar{P}_{\text{reg}} S(\omega) d\omega \quad (3)$$

Time-Domain Analysis

For practical problems for wave energy converters, nonlinearities may come from very different sources: nonlinear wave excitation loads; nonlinear power take-off system (i.e., the nonlinear PTO); nonlinear mooring force (very common if the motions are large!); control system for improving wave energy conversion (when an active control is applied in wave energy conversion, the dynamics is invariantly nonlinear!); or nonlinear restoring force (due to the changes of the area of the water plane) and other nonlinear forces.

A well-accepted time-domain analysis is based on Cummins equation (Cummins 1962) by including the fluid memory effect, and with the Ogilvie relation (Ogilvie 1964), the frequency-domain results can be transformed into the parameters in the Cummins time-domain equation. Such an approach is often termed as a hybrid frequency-time-domain analysis (Taghipour et al. 2008). A modified Cummins time-domain equation for accommodating wave energy conversion can be given as

$$\begin{aligned} [\mathbf{M} + \mathbf{A}] \cdot \ddot{\mathbf{X}}(t) + \int_{-\infty}^t \mathbf{K}(t - \tau) \cdot \dot{\mathbf{X}}(\tau) d\tau \\ + \mathbf{C} \cdot \mathbf{X}(t) \\ = \mathbf{F}_{\text{ex}}(t) + \mathbf{F}_{\text{pto}}(t) + \mathbf{F}_{\text{mooring}}(t) \\ + \mathbf{F}_{\text{control}}(t) \end{aligned} \quad (4)$$

where $\mathbf{A}$ is the frequency-independent added mass matrix (often given as the added mass at infinite frequency); $\mathbf{K}(t)$ the impulse function matrix due to the radiation; $\mathbf{X}(t)$ the motion vector in time domain; $\mathbf{F}_{\text{ex}}$, $\mathbf{F}_{\text{pto}}$, $\mathbf{F}_{\text{mooring}}$, and $\mathbf{F}_{\text{control}}$ the time-dependent vectors for excitation, the PTO force, the mooring force, and the control force.

The transforms between the frequency-domain results and the time-domain parameters are

$$\begin{cases} \mathbf{K}(t) = \frac{2}{\pi} \int_0^\infty \mathbf{b}(\omega) \cos(\omega t) d\omega \\ \mathbf{A} = \mathbf{a}(\omega) + \frac{1}{\omega} \int_0^\infty \mathbf{K}(\tau) \sin(\omega \tau) d\tau \end{cases} \quad (5)$$

The constant added mass $\mathbf{A}$ is often given as the added mass at infinite frequency:

$$\mathbf{A} = \mathbf{a}(\infty) \quad (6)$$

After solving the time-domain equation, the instantaneous power is calculated as

$$P(t) = \mathbf{F}_{pto}(t) \cdot \dot{\mathbf{X}}(t) \quad (7)$$

And the average power conversion over a period of T is given by

$$\bar{P} = \frac{1}{T} \int_0^T P(t) dt \quad (8)$$

Key Applications

Oscillating Water Column (OWC)

An OWC is a specially designed hollow structure (fixed or floating) with an opening in water and an opening to the air. The partially submerged hollow structure forms a water column and an air chamber, separated by a free surface. When a wave passes the hollow structure, the free surface in the hollow structure moves up and down, such that it can compress or decompress the air in the air chamber if the opening to the air is equipped with a power take-off (PTO) system. In a practical OWC, an air turbine can be used to damp the airflow through the upper opening to create the compressed and decompressed air in the air chamber in such a manner that the wave energy is converted into pneumatic energy. The changing pressure in the air chamber could exhale or inhale an airflow through the air turbine PTO and drive the air turbine PTO in a relatively high rotational speed to convert the pneumatic energy into mechanical energy.

As a unique and maybe the largest advantage for the OWC devices as pointed out by Evans and Porter (1995), they may be the only wave energy converters which can effectively overcome the challenges for converting the low-frequency motions in waves (~ 0.1 Hz) into electricity of 50 or 60 Hz. This unique feature allows the PTOs of a high rotational speed to be connected to the generators directly to generate electricity.

Different OWC energy converters have been proposed and studied after the successful OWC navigation buoys with an aim to increase the OWC energy conversion efficiency and capacity for possibly massive wave energy production. These include “Kaimei” (Masuda 1979), Backward Bent Duct Buoy (BBDB) (Masuda et al. 1988) (which is being developed by OceanEnergy Ltd (2017) and currently is in preparation for pre-commercial open sea trials in Hawaii), Spar OWC (Falcao et al. 2012), sloped OWC (Payne et al. 2008), enclosed OWC (Fonseca and Pessoa 2013), as well as the shoreline OWC plants: LIMPET (in decommissioning after generating power to grid for more than 10 years) (Folley et al. 2006), PICO (in decommissioning) (Le Crom et al. 2009; Pecher et al. 2011), and Mutriku (still operational) (EVE 2013). As another successful story in wave energy utilization/production, the LIMPET OWC plant (Scotland, UK), a shoreline OWC wave energy plant, has generated wave power to grid for more than 60,000 h in 2000–2011 (Heath 2012), in a period of slightly over 10 years, and in the last 4 years in its service, the power generation availability reaches 90% (EC 2017). As a pioneer (experimental) wave energy plant, this is a great achievement for the special wave energy technology.

Oscillating Bodies

This category covers a large range of wave energy conversion technologies, including the conventional point absorbers, attenuators, oscillating surging converters, and many other wave energy converters if their body motions are used for wave energy conversion.

Point Absorbers

Point absorbers seem the simplest wave energy converters, which have attracted a lot of attention from researchers and developers, as well as outsiders. The principle of wave energy conversion for point absorbers is very simple and very easy to understand even for people who have no much knowledge about wave energy conversion when he/she watches the up-and-down movements of

the navigation buoys under the wave action in harbors.

Generally, either hydraulic or direct drive power take-offs or other mechanical PTOs can be used to convert the kinetic energy of the device body (bodies) of point absorbers. The well-advanced point absorber technologies include CorPower (fix-referenced point absorber, with built-in control system in the device; see Fig. 2, (CorPower 2017)); CETO (fix-referenced fully submerged point absorber (Rafiee and Fievez 2015)); Wavebob (self-referenced floating point absorber (WaveBob 2011)); OPT (self-referenced floating point absorber (OPT 2015)) and its relevant reference model 3 (RM3 (Yu et al. 2015)); etc.

Attenuators

Pelamis (Yemm et al. 2012), a famous attenuator wave energy converter, may be regarded as the first wave energy converter to reach the pre-commercial level of development, and even three commercial prototypes were manufactured and deployed in the Portuguese coast in 2009 (but no power has been generated yet) based on the report (EC 2017). The later version (P2) has been

tested in EMEC with the financial support from Eon and Scottish Renewables. The company had finally run into administration in 2014, and Wave Energy Scotland (WES) has bought all IPs from the company (EC 2017).

A slightly different form from Pelamis, the raft-type attenuator wave energy converters are now being developed by some organizations, including M4M developed at the University of Manchester, UK, (M4M 2015) and SeaPower in Ireland (SeaPower 2015). Numerical modelling technologies have been widely applied for the attenuator wave energy converters (Zheng et al. 2015) (Fig. 3).

Oscillating Surging Services

The Oyster device is an oscillating surging device, developed by Aquamarine Power (Whittaker and Folley 2012). Such an oscillating surging device is reported to have a high energy conversion efficiency (Babarit et al 2012), and an additional benefit could be a possible low initial building cost of the device since it is basically regarded in a 2D extension, rather than a 3D extension like many other devices if a larger device is expected. A significant challenge is the structural reliability

Wave Energy Converters, Fig. 2 CorPower point absorber wave energy converters (CorPower 2017)

Wave Energy Converters, Fig. 3 Pelamis 2 in waves. (From EMEC website: <http://www.emec.org.uk/about-us/wave-clients/pelamis-wave-power/>)

Wave Energy Converters,

Fig. 4 Oyster device in waves. (Adopted from website: <https://oregonshores.org/article/rules-ocean-energy-siting-are-horizon>)

of such a device, since it is found that the device is frequently plunged into water ahead the wave action (see Fig. 4), indicating large wave slamming forces on the device.

Overtopping Devices

Tapchan

Tapchan is a fixed overtopping wave energy plant, one of the two pioneer wave energy plants in Norway in the 1980s (in the same period, a fixed OWC plant was built a few hundred meters away, both on the west coast of Norway). Accordingly, this prototype wave energy converter has the following features:

- The wave energy is converted to potential energy in an onshore water reservoir.
- The generation of electricity is carried out by a standard hydroelectric power plant technology.

Wave Energy Converters, Fig. 5 Tapchan wave energy plant. (Adopted from (Falcao 2014))

Wave Energy Converters, Fig. 6 Wave Dragon 1:4.5 model tested in sea. (Adopted from the Internet)

- The conversion device is entirely passive and has no moving parts (except the water turbine).
- High energy conversion efficiency can be maintained over a broad range of wave heights, frequencies, and directions.

The plant was destroyed by a winter storm in 1988 (see https://www.youtube.com/watch?v=vG6R_R2YyAo) (Figs. 5 and 6).

Floating Overtopping WECs

Wave Dragon is a floating overtopping wave energy converter. From the literature, this device may have so far the highest power rating in all single wave energy converters: 12MW (<http://www.wavedragon.net/>). A proposed full-scale Wave Dragon with a 7MW rated power is a huge device, with an overall length of 350m between two arms and a displacement of 40,000 m³. In the development, the concept has finished a 1:4.5 scale sea trial in the test site in Nissum Bredning, Denmark (Kofoed et al. 2006).

Synonyms

Wave energy converters; WEC

Definition

Wave energy utilization buoy is a floating power station for generating electrical energy from wave power. The buoy devices being developed include: Powerbuoy, OE buoy, RM3, IPS buoy, and so on. (The examples shown here are not intended to form an exhaustive list and were chosen among the projects that reached the prototype

stage or at least were object of extensive development effort.)

Scientific Fundamentals

A Brief Overview of Buoy Wave Energy Device

Wave energy is a type of well-concentrated renewable energy when compared to other types of renewable energy (such as solar, wind, etc.). The wave energy resources are huge, utilizing wave energy is desirable in many countries around the world, especially in the countries with long coastal lines and rich wave energy resources.

Wave energy researchers and developers have been working in solving the practical problems in wave energy extraction for many years. Though some early optimistic predictions in capturing large wave energy from seas at a competitive rate (for example, 2GW wave power plant producing power at a rate of 1.3 p/kWh has been described in Whittaker et al. 1985) have not been reached, the research and development of wave energy conversion have made a great deal of progress, and some of the wave energy devices have reached the stages of full-scale pre-commercial or large-scale sea trials. For instance, in 2009, a 1:2.5 scale OE Buoy device (an oscillating water column (OWC) device) finished a sea trial for a period of over two and half years in Galway Bay. (Ocean Energy Ltd. 2018) Recently, OceanEnergy announced its pioneering wave energy convertor OE Buoy will be built by Oregon-based Vigor and deployed at the US Navy's Wave Energy Test Site on the windward coast of the Hawaiian Island of O'ahu in the fall of 2018, the 826-ton OE Buoy measures 125×59 feet with a draft of 31 feet and has a potential rated capacity of up to 1.25 MW in electrical power production (Wave Energy Conversion Pioneer 2018). More wave energy devices and their developments can be found in Refs. (Falcão 2010; ISSC Specialist Committee 2009)

In the development of wave energy, nearshore or shallow water regions are frequently considered for developing wave energy converters/farms due to the closeness to the shore and the easy

infrastructure, for instance, the cable connection and the availability for the operation and maintenance. One important aspect of these developments is the availability of wave energy resources in shallow water regions. Folley and Whittaker (2009) have shown that the wave resources reduce by less than 10% when traveling from a water depth of 50 m to 10 m. Hence the development of wave energy in shallow water regions has been preferred. So far most of the installed wave energy converters are deployed in the water depths of less than 50 m, and most of the proposed wave farms are deployed in the water depths of less than 100 m. Similarly, Johanning et al. (2007) concluded that wave energy converters (WECs) would be very likely installed in the shallow to intermediate depths, typically at around 50 m contour in the open areas for wave energy production.

Point absorbers may be the simplest floating buoy wave energy converters, and the main motion mode for power conversation is heave, though other motion modes may contribute to small part of the power conversation. The horizontal dimensions of point absorbers are much smaller than the wavelength, the known devices are Power Buoy, (OPT 2018a) the US reference model (RM3, Yu et al. 2015; Prendergast et al. 2018) and RM6, (Bull et al. 2014; Sheng 2019a), and so on. The main motions of point absorbers are the relative heave motions between buoy and referenced damping panel (or referenced to the sea bed). It is quite straightforward for the cases with only considering the relative heave motions (Falnes 1999a and Sheng and Lewis 2016a).

Scientific Fundamentals

The study of the hydrodynamics of floating wave energy converters could benefit from previous studies on the, largely similar, dynamics of ships in wavy seas, that took place in the decades preceding the mid-1970s. The presence of a power take-off mechanism (PTO) and the requirement of maximizing the extracted energy introduced additional issues.

In this section, we will take the single buoy wave energy converter as an example to illustrate how the device extracts wave energy from regular

Wave Energy Utilization Buoy, Fig. 1 Wave energy converter. Figure from (Faedo et al. 2017)

(sinusoidal) waves and converts it into electrical energy. Detailed information on wave energy utilization can be found in the literature (Falcao 2010). The oscillation system consists of a half-immersed sphere and a linear PTO with one end anchored in the sea bed, as shown in Fig. 1.

Theoretical and Numerical Modeling

We assume the waves with small amplitude, which allowed the linearization of the governing equations and the use of the frequency-domain analysis. The hydrodynamic forces on the wetted surface of the body were decomposed into excitation forces (due to the incident waves), radiation forces (due to body motion), and hydrostatic forces (connected with the instantaneous position of the floating body with respect to the undisturbed free surface). As shown in Fig. 1, the body position is defined by the vertical coordinate x (with $x = 0$ in calm water), the equation of motion is

$$(m + A)\ddot{x} = f_d - B\dot{x} - \rho g S x + f_{PTO} \quad (1)$$

where, $f_d(t)$ is the vertical component of the excitation force (acting on the assumedly fixed body,

$f_d = 0$ in calm water), $f_{PTO}(t)$ is the vertical force due to the PTO mechanism, $A(\omega)$ is the hydrodynamic coefficient of added mass (accounting for the inertia of the water surrounding the body), $B(\omega)$ is the radiation damping coefficient (accounting for the damping on the body due to energy transfer to waves radiated away), and S is the cross-sectional area of the body by the unperturbed free surface plane ($\rho g S x$ is the hydrostatic restoring force).

We assume the PTO force to consist of a linear damper (coefficient C) and a linear spring (stiffness K):

$$f_{PTO} = -C\dot{x} - Kx \quad (2)$$

Then the whole system becomes fully linear.

In regular waves of amplitude A_ω and frequency ω , we write $\{x, f_d\} = \text{Re}(\{X, F_d\}e^{i\omega t})$, where X and F_d are complex amplitudes and $\text{Re}()$ means real part of. Then, from eq. 1, we obtain

$$X = \frac{F_d}{-\omega^2(m + A) + i\omega(B + C) + \rho g S + K} \quad (3)$$

Since the system is linear, the excitation force is proportional to wave amplitude, i.e., $|F_d| = \Gamma A_\omega$, where $\Gamma(\omega)$ is a hydrodynamic coefficient of diffraction force. The time-averaged absorbed power is $\bar{P} = \overline{f_d \dot{x}} = C\omega^2 |X|^2 / 2$, which can be written as

$$\bar{P} = \frac{1}{8B} |F_d|^2 - \frac{B}{2} \left| U - \frac{F_d}{2B} \right|^2 \quad (4)$$

where $U = i\omega X$ is the complex amplitude of the velocity $\dot{x}$.

For a given body and given incident regular wave, B and F_d are fixed. Then the absorbed power $\bar{P}$ depends on X , i.e., on the PTO damping and spring coefficients C and K . The maximum value equal to

$$\bar{P}_{max} = \frac{1}{8B} |F_d|^2 \quad (5)$$

occurs for $U = F_d/2B$, then combined Eq. 3 we obtain the two optimal conditions,

$$\omega = \left(\frac{\rho g S + K}{m + A(\omega)} \right)^{1/2} \quad (6)$$

$$C = B(\omega) \quad (7)$$

Equation 6 is a resonance condition: its right-hand side is the frequency of free oscillations of an undamped mechanical oscillator of mass $m + A$ acted upon by a spring of stiffness $\rho g S + K$. Equation 7 shows that the optimal PTO damping should equal the radiation damping.

In regular waves, the averaged wave energy density, P_w (per unit surface area) over a wave period is given by

$$P_w = \frac{1}{2} \rho g A^2 \quad (8)$$

where A is the amplitude of regular waves. We define the capture width $l = \bar{P}/P_w$, for a body with a vertical axis of symmetry (but otherwise arbitrary geometry) oscillating in heave, it can be shown that

$$l_{max} = \frac{\bar{P}_{max}}{P_w} = \frac{\lambda}{2\pi} \quad (9)$$

where λ is the wavelength. If the body oscillates in sway $l_{max} = \frac{\lambda}{\pi}$ equation 9 is an important theoretical result, obtained independently in 1975–1976 by Budal and Falnes, Evans, Newman, and Mei, (Falcao 2010) on the maximum power that can be absorbed from the waves, as is the well-known Betz limit for the power coefficient of wind turbines.

Maximum Wave-Power Absorption Under Motion Constraints

In practice, most wave-energy devices will have physical limitations placed upon their excursions due to restraints such as mooring lines or piston stroke. Whereas there exists a significant band of wave frequencies and lengths for which the device does not reach these limits, in long waves a relatively small device would, ideally, need to make large excursions to achieve optimum power absorption. Again, larger amplitude waves require larger device excursions for optimum absorption. Evans D V (1981) proposed a simple expression

for the maximum efficiency of power absorption of a buoy when its velocity and hence amplitude is constrained such that its magnitude never exceeds a given multiple of the incident wave amplitude and also for a system of absorbing bodies under global velocity constraints. Here we will briefly demonstrate his conclusion.

We consider a regular incident wave condition in a frequency of ω , N independently oscillating buoys making simple harmonic motions response to the wave also in the frequency of ω , and each buoy can absorb energy from the incident wave field. Let $\mathbf{U}$ be the complex N -vector denoting the amplitude and phase of the velocity of each buoy, and $\mathbf{B}$ the $N \times N$ real, symmetric radiation damping matrix. Let $\mathbf{F}$ be the complex N -vector denoting the amplitude and phase of the exciting force on each buoy in its direction of subsequent motion, when all buoys are held fixed. Then the optimized energy absorption can be shown as:

$$\begin{aligned} P_{max}(\mathbf{U}) &= \frac{1}{2} \mathbf{U}^* (\mathbf{B} + 2\mu \mathbf{I}) \mathbf{U} \\ &= \frac{1}{8} \mathbf{F}_s^* \left[\mathbf{B}^{-1} - \mathbf{B}^{-1} (\mathbf{B} + \mu \mathbf{I})^{-2} \mu^2 \right] \mathbf{F}_s \end{aligned} \quad (10)$$

for

$$\beta \leq \frac{1}{2} \|\mathbf{B}^{-1} \mathbf{F}_s\| = \|\mathbf{Y}\| \quad (11)$$

where $*$ denotes conjugate transpose, β is the constraints of the buoys, μ determined by $\mathbf{U}^* \mathbf{U} = \beta^2$ and $\mathbf{U} = (\mathbf{B} + \mu \mathbf{I})^{-2} \mathbf{B} \mathbf{Y}$, $\mathbf{Y} = \frac{1}{2} \mathbf{B}^{-1} \mathbf{F}$.

We assume each of the N buoys have constraints on their amplitudes and velocities which may be of the form:

$$|U_i| \leq \omega A \alpha_i = \beta_i \quad (i = 1, 2, \dots, N) \quad (12)$$

where A is the incident wave amplitude and α_i are constants governing the permissible buoy amplitude compared to the incident wave amplitude. In normal operating conditions $\alpha_i = 0(1)$ but in larger waves α_i may be small.

We define the capture width $l = P/P_w$, for a vertically oscillating buoy with a vertical axis of symmetry,

$$l_{max} \equiv \frac{P_{max}}{P_w} = \frac{\lambda}{2\pi} \left\{ 1 - H(1 - \delta)(1 - \delta)^2 \right\} \quad (13)$$

where

$$\delta = \frac{2\omega A \alpha B}{|F|} = \alpha \left(\frac{2M}{\rho a^3} \right)^{\frac{1}{2}} (Ka)^{\frac{3}{2}} \lambda_{33}^{\frac{1}{2}} \quad (14)$$

where K is the wave number, ρ is the density of sea water, a is the radius of the buoy, and λ is the damping coefficient in heave, nondimensionalized with respect to a typical mass, M .

Figure 2 Evans 1981 shows the variation of $l_{max}/2a$ with Ka for different α_i of a half-immersed sphere. It can be seen that, if the amplitude of motion of the sphere is not allowed to exceed the wave amplitude the capture width never exceeds 70% of the sphere diameter in contrast to the result from unconstrained motions where l_{max} increases indefinitely as $Ka \rightarrow 0$. For sphere amplitudes up to twice the wave amplitude ($\alpha = 2$), l_{max} peaks at a value 108% of the sphere diameter showing that energy is being absorbed from outside the region

occupied by the sphere. In steeper waves where the ratio may have to be as small as $\alpha = 0.5$ the captured width never exceeds 40% of the sphere diameter.

Open Sources for WEC Simulation

WEC-Sim (Wave Energy Converter SIMulator) is an open-source wave energy converter simulation tool. The code is developed in MATLAB/SIMULINK using the multibody dynamics solver Simscape Multibody. WEC-Sim has the ability to model devices that are comprised of rigid bodies, power-take-off systems, and mooring systems. Simulations are performed in the time-domain by solving the governing WEC equations of motion in 6 degrees of freedom.

WEC-Sim is a collaboration between the National Renewable Energy Laboratory (NREL) and Sandia National Laboratories (Sandia), funded by the US Department of Energy's Water Power Technologies Office. Due to the open-source nature of the code, WEC-Sim has also had many contributions from external

Wave Energy

Utilization Buoy,

Fig. 2 Variation of maximum capture width/diameter ratio with wave length for half immersed energy absorbing sphere for different motion constraints. The dashed line denotes unconstrained sphere (Evans 1981)

collaborators. For more details see (Wave Energy Converter SIMulator 2018).

Key Applications

There is a wide variety of wave energy utilization technologies, resulting from the different ways in which energy can be absorbed from the waves, and also depending on the water depth and on the location (shoreline, nearshore, offshore). Several methods have been proposed to classify wave energy systems, according to location, to working principle, and to size (“point absorbers” versus “large” absorbers).

The classification in Fig. 3 (Falcao 2010) is based mostly on working principle. The floating devices can be classified as wave energy utilization buoy. The examples shown are not intended to form an exhaustive list and were chosen among the projects that reached the prototype stage or at least were object of extensive development effort.

A few devices are briefly described in the following section.

OE Buoy (BBDB OWC, RM6)

OE Buoy is an Oscillating Water Column wave energy converter deployed by the HMRC (The Hydraulics and Maritime Research Centre) in Cork, Ireland, and is now owned and developed by the company OceanEnergy. The OE Buoy is a version of a device known as the Backward Bent Duct Buoy (BBDB) which was invented in 1986 by wave energy pioneer and Japanese naval commander Yoshio Masuda et al. 1988. It was deployed in half-scale test mode in Spiddal near Galway in Ireland for over 2 years between 2007 and 2009. As of March 5, 2011, the model has been redeployed at the same site, primarily as a data collector for the EU-funded Cores Project. The full-scale pioneering OE buoy developed by OceanEnergy will be built by Oregon-based Vigor and deployed at the US Navy’s Wave Energy Test Site on the windward coast of the Hawaiian Island

Wave Energy Utilization Buoy, Fig. 3 The various wave energy technologies (Falcao 2010). The floating devices can be classified as wave energy utilization buoy

Wave Energy Utilization Buoy, Fig. 4 RM6 BBDB device design and dimensions and wells turbine schematic. The width of the device (not shown) is 27 m (Bull et al. 2014)

of O'ahu in the fall of 2018 (Wave Energy Conversion Pioneer 2018).

RM6 reference model (see Fig. 4) is an oscillating water column wave energy converter developed by Sandia National Laboratories using a combination of numerical modeling tools and scaled physical models (Bull et al. 2014). Bull et al. (2015) studied the US RM6 BBDB oscillating water column wave energy converter, providing some insights on the BBDB wave energy converters on the optimization of the air turbine PTO, as well as the electricity generation. The systematic study of the power performance of BBDB OWC devices can be found in the literature (Sheng and Lewis 2018, 2016b; Sheng 2019b).

Reference Model 3 RM3 is essentially a two-body floating (self-referenced) point absorber, it can also be considered as a fix-referenced PA when the damping panel is fixed (no motion is allowed for it). The following section will take RM3 as an example to illustrate the basic principle of wave energy device conversion of wave energy.

The original design of RM3 is shown in Fig. 5. This point absorber consists of two main moving bodies: the surface float of diameter 20 m with a small draft, and the vertical column which is connected to a large reaction plate (30 m in diameter). Overall, the point absorber has a draft of

30 m, and the displacements 848.2 m^3 and 680.8 m^3 for the vertical column (the cylinder and the reaction plate has been simplified as zero thickness) and for the surface float, respectively.

The surface float moves up and down the vertical column in response to the motion of the waves. The reaction plate maintains the vertical column in a relatively stationary position. The relative motion of the surface float with respect to the vertical column drives a mechanical system contained in the vertical column that converts the linear motion of the surface float into a rotary one. The rotary motion drives electrical generators that produce electricity for the payload or for export to nearby marine applications using a submarine electrical cable. This high-performance wave energy conversion system generates power even in moderate wave environments.

In converting wave energy, the surface float will very much move in-phase, while the vertical column moves out-of-phase with the passing waves. These in-phase and out-of-phase motions could generate a large relative motion between these two bodies, thus providing good motions for converting wave energy. In the case of a fix-referenced RM3, the vertical column can be taken as a fixed structure.

It will be seen that for a floating PA with its relative motions between the moving components being used, it could be beneficial for improving its wave energy conversion efficiency, as well as its

Wave Energy Utilization Buoy, Fig. 5 The RM3 point absorber wave energy converter (Yu et al. 2015).

compliance thus its survivability in the extreme waves (with long wave periods).

Following (Sheng and Lewis 2016a), for such floating/self-referenced WECs, the heave motions of the two-body systems are normally

independent of the other motion modes, especially when the motions are small. For power conversion, the relative heave motions of the two bodies are taken, and the corresponding dynamic equation can be expressed as:

$$\begin{cases} [i\omega Q_{33} + b_{33} + B_{33}]v_3 + [i\omega Q_{39} + b_{39}]v_9 = f_3 - B_{pto}(v_3 - v_9) \\ [i\omega Q_{93} + b_{93}]v_3 + [i\omega Q_{99} + b_{99} + B_{99}]v_9 = f_9 + B_{pto}(v_3 - v_9) \end{cases} \quad (15)$$

with

$$\begin{cases} Q_{33} = (m_{33} + a_{33}) - \frac{c_{33}}{\omega^2}; Q_{39} = a_{39} - \frac{c_{39}}{\omega^2} \\ Q_{93} = a_{93} - \frac{c_{93}}{\omega^2}; Q_{99} = (m_{99} + a_{99}) - \frac{c_{99}}{\omega^2} \end{cases} \quad (16)$$

where B_{pto} is the damping coefficient of the PTO for the RM3 device; b_{33} , b_{39} , b_{93} , and b_{99} are the radiation damping coefficients due to the body motions; B_{33} and B_{99} the additional linear damping coefficients caused by the heave motion

of the bodies; f_3 and f_9 the complex excitations for the heave motions of both moving bodies of the device; v_3 and v_9 the velocities of the heave motions; m_{33} and m_{99} the mass of each body; a_{33} , a_{39} , a_{93} , and a_{99} the self- and cross-term added masses related to the heave motion of two bodies; and c_{33} , c_{39} , c_{93} , and c_{99} the corresponding restoring force coefficients for the device.

The average power conversion is then given by Eq. 17 below,

$$\overline{P} = \frac{1}{2} B_{pto} |v_9 - v_3|^2 \quad (17)$$

with the relative velocity solved from Eq. 15, the average power is,

$$\overline{P} = \frac{1}{2} B_{pto} \frac{Z_1^2 + Z_2^2}{(Y_1 + Y_2 B_{pto})^2 + \omega^2 (Y_3 + Y_4 B_{pto})^2} \quad (18)$$

In the above equation Y_1 , Y_2 , Y_3 , and Y_4 are

$$\begin{cases} Z_1 = f_{3r}(b_{99} + B_{99} + b_{93}) - f_{9r}(b_{33} + B_{33} + b_{39}) - \omega f_{3i}(Q_{99} + Q_{93}) + \omega f_{9i}(Q_{33} + Q_{39}) \\ Z_2 = f_{3i}(b_{99} + B_{99} + b_{93}) - f_{9i}(b_{33} + B_{33} + b_{39}) + \omega f_{3r}(Q_{99} + Q_{93}) - \omega f_{9r}(Q_{33} + Q_{39}) \\ Y_1 = (b_{33} + B_{33})(b_{99} + B_{99}) - b_{93}b_{39} - \omega^2(Q_{33}Q_{99} - Q_{93}Q_{39}) \\ Y_2 = b_{33} + B_{33} + b_{99} + B_{99} + b_{39} + b_{93} \\ Y_3 = (b_{33} + B_{33})Q_{99} + (b_{99} + B_{99})Q_{33} - b_{93}Q_{39} - b_{39}Q_{93} \\ Y_4 = Q_{33} + Q_{99} + Q_{39} + Q_{93} \end{cases} \quad (19)$$

where the subscripts r and i denote the real and imaginary parts of the excitation forces f_3 and f_9 .

Based on the Eq. 18, an optimized PTO damping for maximizing the wave energy conversion for the wave of a given frequency can be obtained in Eq. 20 and the corresponding maximized power conversion in Eq. 21.

$$B_{pto} = \sqrt{\frac{X_1^2 + \omega^2 Y_1^2}{X_2^2 + \omega^2 Y_2^2}} \quad (20)$$

$$\overline{P}_{max} = \frac{1}{4} \frac{Z_1^2 + Z_2^2}{X_1 X_2 + \omega^2 Y_1 Y_2 + \sqrt{(X_1^2 + \omega^2 Y_1^2)(X_2^2 + \omega^2 Y_2^2)}} \quad (21)$$

The optimized PTO damping and the maximal converted wave energy both vary depending on frequency; hence this optimized condition may only be useful in the regular waves, where the wave frequencies are constant for a given wave. Figure 6 shows the comparison of the maximal capture powers for the fix-referenced and self-referenced PAs (“fix-referenced” and “self-referenced” in the legend) and the self-referenced devices are with two different reaction plates ($D = 25$ m and $D = 30$ m), more details can be found in Sheng and Lewis (2016a).

PowerBuoy

PowerBuoys are manufactured by Ocean Power Technologies (OPT) in Pennington, New Jersey

reactance-dependent damping coefficients and Z_1 and Z_2 are radiation damping and excitation-based values that are calculated using Eq. 19 as:

(OPT 2018b) (see Figs. 7 and 8). The outline of the PowerBuoy design process is illustrated by examples from recent development efforts in (Edwards and Mekhiche 2014), which attempts to address the complex multidiscipline and concurrent engineering process required to successfully design, develop, test, and validate of OPT’s PowerBuoy. OPT’s PowerBuoy portfolio includes two power output ranges: up to 3 kW and up to 15 kW, the average output power is deployment-site dependent. OPT’s products serving the off-shore power needs are the PB3 (commercial ready) and the PB15 (under development). Product specifications for the PB3 are shown in Fig. 9. OPT’s PB3 was designed acting as an uninterruptable power supply (UPS) which

Wave Energy Utilization Buoy,

Fig. 6 RM3 maximal capture powers in regular waves ($D = 25$ m and $D = 30$ m) (Bull et al. 2014).

Wave Energy Utilization Buoy, Fig. 7 PowerBuoy cross sectional view (Parsa et al. 2017)

constantly recharges itself by harvesting energy from the waves. It was developed for offshore remote autonomous applications such as the ones found in the oil and gas industry. It was ocean-deployed, moored, and floats over the point of use and can operate in any ocean depth over 20 meters and up to 1000 meters. In July 2016, OPT deployed its first commercial PB3 PowerBuoy off the coast of New Jersey (Ocean Power Technologies 2018; Parsa et al. 2017)

Considering the levels of validation and maturity that have been achieved through full-scale ocean deployments and accelerated life testing, and based on the American Petroleum Institute (API) Technology Readiness Scale (TRL) of 7 (API 17 N), the PB3 was estimated to have achieved a TRL6.

IPS Buoy

The IPS Buoy is a system for generating electricity from ocean waves designed by two Swedish companies, Interproject Service AB (IPS) and Technocean (TO).

Figure 10 shows the working principle of the IPS OWEC Buoy. As the buoy A moves up and down with waves, the acceleration tube B, which is open in both ends, will move vertically relative to the water column in it. The water column will “trap” the piston C, forcing it to move relative to the acceleration tube. This pumping motion is mechanically or hydraulically transformed to a rotary motion driving a generator D.

A typical IPS OWEC Buoy consists of a round 6–8 meter buoy floating, a 20 meter underwater acceleration tube with a piston, and an energy conversion machinery including an electric generator. The buoy is typically located in 50–100 meters deep water and anchored via a slack mooring arrangement. One such buoy built for 120 kW mean output may produce up to 1.0 GWh

Wave Energy Utilization Buoy, Fig. 8 Two PB3 as deployed in the ocean in surface expression (Parsa et al. 2017)

DIMENSIONS	ELECTRICAL
Height: 13.3 m	Continuous Average Power based on 8.4 kWh/Day (typical) (Annual Average: Site Dependent)
Draft: 9.28 m	Payload Peak Power: up to 3 kW peak power to load: 7.5 kW (custom)
Spar Diameter 1.0 m Float Diameter: 2.65 m	Nominal Battery Capacity (ESS): 50 kWh (approx.); Modular and Scalable to 100, 150 kWh (appx.)
Weight: 8,300 kg	Zero wave day capacity: 100 W load for 1+ weeks (50 kWh ESS)
MOORING	DC Output: 24 V and 300 V (standard) 5 V to 600 V (custom)
Type: Single point or 3 point	Power Generation Sea States: 1 - 5
Point: Anchor or shackle

Max Depth w/ standard design: 1,000 m*	*Other mooring designs available for deeper deployments

Wave Energy Utilization Buoy, Fig. 9 Product specifications for the PB3 (OPT 2018c)

annually. In the waters west of Scotland and Ireland where the power “content” in the waves is in the order of 50 ~ 70 kW/m wavefront, a 10 m IPS

OWEC Buoy will reach a power of 150–250 kW and produce more than 1.4 GWh of electric energy per year The IPS OWEC Buoy (2018).

Wave Energy Utilization Buoy, Fig. 10 Working principle of the IPS OWEBC Buoy

The piston slides along the central part of the tube that needs to limit the stroke of the piston at both ends. Falcão A F O et.al (2012) proposed using a hydraulic turbine inside the tube to solve the problem of the end-stops, as shown in Fig. 11. In such situations, the dynamics of the IPS buoy can no longer be theoretically modeled as Falnes (1999b) did for a two-body heaving system or as done in (Falcão AF de et al. 2008) for the IPS buoy, for the cross-section of the acceleration tube is nonuniform, the flow inside the tube is also nonuniform, the inertia of the enclosed water cannot be represented by that of a solid body. Besides, apart from the axial force on the piston (or on the hydraulic turbine), the extra-axial force on the noncylindrical inner walls of the tube must be accounted for.(Falcão et al. 2012)

In regular waves, for a given buoy and given tube diameter and diameter ratio, maximum wave energy absorption is attained by an infinite number of tube combination mass (tube mass plus tube added mass) tube length and PTO damping coefficient. While in irregular waves, the performance was found to be much poorer (no phase control is considered), even if the tube combination mass,

Wave Energy Utilization Buoy, Fig. 11 IPS buoy with the piston replaced by a hydraulic turbine. (Falcão A F O et al. 2012)

the tube length, and the PTO damping coefficient are optimized. The use of a hydraulic turbine in the tube instead of a piston was found in general to result in poorer wave energy absorption and to require a longer tube (Falcão et al. 2012).

The Sloped IPS Buoy

The sloped IPS buoy concept was developed by Edinburgh University as a device that would replace the Solo Duck(Salter 1974) as a confidence-building step in wave energy technology (Salter and Lin 1995). It is based on the axisymmetrical device designed by Interproject Services (IPS). The device is an inclined flat plate with a curved head (approximately 30 m wide and 6 m from front to back), which is inclined at an angle to the vertical (see Fig. 12 and Table 1, Thorpe 1999). The long tail is open to the sea at the bottom and is mainly empty, except for bracing plates. This adds a large inertia to movement in all directions, except for “slope” (i.e., back and forth in the direction of the tail). In this mode, the plates are edged on to the movement and so offer minimal resistance. An important feature of the buoy is the flared ends of the tube containing the water piston. When the movement of the piston exceeds the length of the

Wave Energy Utilization Buoy, Fig. 12 Shape and side view of the sloped-IPS Buoy (Thorpe 1999)

Wave Energy Utilization Buoy, Table 1 Summary of the characteristics of the sloped-IPS Buoy (Thorpe 1999)

Device width	30 m
Directionality factor	0.94
Mean power	1495 kW
Capture efficiency	81%
Power captured	1212 kW
Conversion efficiency	92%
Generator efficiency	88%
Availability	90%
Average power out	985 kW
Annual output	7.77 GWh

narrower part of the tube, it will enter the wider section allowing water to flow past it more easily. This flow effectively decouples the piston from the large inertia of the water mass in the tail. This arrangement avoids the shock loading that “end stops” can cause.

Salter and Rampen (1993) designed the “wedding cake” multieccentric radial piston hydraulic machine for the sloped IPS buoy, but the piston will be operating in seawater so the durability of the device needs to be assessed specially. Taylor J R M and Mackay I (2001) designed an eddy current dynamometer for the Swedish free-floating sloped-IPS buoy and optimized the sloped-IPS buoy models so that the detailed

response data can be collected for a very wide range of sea conditions.

More details of numerical simulation about sloped-IPS Buoy can be found in (Payne et al. 2006, 2015).

Summary

The ocean has a rich reserve of wave energy. So far, thousands of WEC patents have been proposed or put into practice, the number does not seem to be decreasing: new concepts and technologies replace or outnumber those that are being abandoned. All forms of devices should focus on cost, availability, and survivability to improve the industrial readiness level for large-scale commercial applications.

Synonyms

Navy oceanographic meteorological automatic device; NOMAD; Ocean data acquisition system; ODAS; Waverider buoy; Wavescan buoy; Weather buoy

Definition

Wave measurement buoys are the special buoys which are commissioned to measure the ocean

waves (the modern wave measurement buoys may also collect the meteorological and oceanographic data, depending on the purposes of the wave measurement buoys). In most cases, the wave measurement buoys are anchored at seabed to allow some motions so to reduce the environmental loads acting on the buoy (see Fig. 1).

Scientific Fundamentals

Nowadays, wave measuring buoys are essential devices in many applications. Many national and international meteorological and oceanographic services monitor ocean wave characteristics nearly continuously over great expanses of the world's coastlines and in deep waters. These provide important information for mariners, fishermen, offshore oil workers, weather forecasters,

Wave Measurement Buoy, Fig. 1 Wave measurement and communications. (Adopted from website: <https://www.bosai-jp.org/en/solution/detail/29/category>)

ocean engineers, harbor authorities, coastal managers, marine scientists, and the public-at-large planning, coordinating, and conducting a variety of maritime activities.

The wave measurement buoys are normally anchored to the seabed using a single point mooring system (Fig. 1), which could provide enough flexibility for the motion of the buoy, allowing the buoy following the water particle motions, and therefore, the buoy's heave motion can be assumed to be the wave elevation (details can be seen in the following section).

It should be noted that in many cases, the wave measurement buoys may have equipped with many sensors to measure other environmental and oceanographic parameters for providing more information to different users as mentioned above.

One of the advantages for the wave measurement buoys for measuring waves is their capability in long-term measurement: the measured data can be transformed using the direct radio communication or via a satellite (see Fig. 1); and the wave measurement is subject to battery life, and that is why the wave measurement buoys are equipped with solar panels.

Principle of Wave Measurement Using Wave Buoy

The wave measurement buoys measure the ocean waves on the assumption that the buoys follow the water particles traveling on a circular orbit (in deep water conditions). A good example is shown in Fig. 2 (WaveRider wave measurement buoy). The main measurement unit is the accelerometer which is located on a stabilized platform, so it could measure the up-and-down motion of the buoy (in a nautical term as heave motion), rather than the motions of all 6 degrees of freedom (6-DOFs). The accelerometer measures the heave acceleration, and the double integration of it would lead to the motion of the buoy.

It should be noted that the wave measurement buoys follow the water particle motion only for certain wave lengths/periods. The RAO (response amplitude operator) of the heave motion for the 0.9 m WaveRider is shown in Fig. 3. It can be seen that when the wave period is larger than 2.5 s, the

Wave Measurement Buoy, Fig. 2 Setup of the WaveRider buoy (website figure)

RAO is very close to 1.0 (equal to 1.0 when the wave period is larger than 3.0 s). The unit RAO means that the heave motion of the WaveRider buoy is same as that of the wave elevation.

When wave period is smaller than 3.0 s, an appropriate correction must be applied to get the correct relation between the buoy's heave motion and the wave elevation.

Another important factor is the buoy's phase response ("red line" in Fig. 3). When the wave period is larger than 1.7 s, the buoy's heave motion is in phase with the wave elevation, and for the shorter waves, there will be a large response phase between the heave motion and wave, for which the correction would be much more difficult and the measurement accuracy may be limited (it is also subject to the damping level of the buoy in waves).

Comparison of Wave Buoys and Other Wave Measurements

One question may be asked that whether the wave measurement buoys can measure the wave accurately. For instance, whether the wave measurement buoys could follow the water particles or whether the buoy could avoid the large wave peaks (3-D waves). To answer this question there

Wave

Measurement Buoy,

Fig. 3 WaveRider buoy response to wave excitation (WaveRider diameter: 0.9 m)

Wave Measurement Buoy, Fig. 4 Wave measurements buoys used in WADIC project

are many comparisons of the wave buoys to other measurement methods.

In the WADIC project (Allender et al. 1989), seven different wave measurement buoys (Fig. 4) are used for the comparisons of wave measurements, including wavestaff, wave radar, and laser measurement. The conclusion is that all the

measurements are reassuringly good, and the large differences are found mostly for swells, high frequency waves (0.2–0.5 Hz), and the extreme sea states.

In another research work, Liu et al. (2015) studied the wave measurements using wave measurements in laboratory condition. Two wave

buoys are, namely WaveScan (1:8 & 1:16) and ODAS (1:11.25), used for comparisons with the wave measurements of wave probes in the wave tank. The data analysis has shown that the wave buoys measure waves in a very good agreement with the measurements of wave probes.

In a recent survey in 2010, Mettlach and Teng (2010) examined the ocean wave measurements around the world, and it is found that the nearly all wave buoys use onboard accelerometers for measuring waves; however, Japan, the Netherlands, South Africa, and the USA have experimented with GPS and D-GPS to produce wave measurements.

Key Applications

WaveRider Buoy

The Waverider buoys, developed by Datawell BV (<http://www.datawell.nl/products/buoys.aspx>), use the same sensors in the well-known Directional Waverider MkI, II, III, and 4. For the directional WaveRider 4 (Fig. 5), its sample frequency of the data processing is doubled to 2.56 Hz. The high frequency limit of the heave and direction signals is shifted from 0.58 to 1.0 Hz. With this choice, the high frequency limit of the wave buoy is determined by the hydrodynamic response of the hull, not by the onboard instrumentation. In addition, the DWR4 transmission protocol allows for a superior heave and horizontal displacement resolution. Following is the list that displays the features of Waverider buoys.

- Wave motion sensor based on a stabilized platform, accelerometers, and magnetic compass
- Measures wave height for wave periods of 1–30 s, accuracy 0.5% of measured value
- Measures wave direction
- Measures surface current
- Measures water temperature
- GPS for buoy monitoring and tracking through HF link
- Internal logger
- Power switch
- LED flash antenna

Wave Measurement Buoy, Fig. 5 WaveRider buoy

- 0.9 m (0.7 m) diameter spherical hull of AISI 316 including eccentric mooring eye
- Optional Cunifer hull, warranted not to corrode
- 1.6 years (10 months) battery life
- Optional HF transmitter range 50 km over sea
- Optional Iridium SBD module for ocean wide coverage and unlimited range
- Optional Iridium Internet module
- Optional Argos module for ocean wide coverage and unlimited range
- Optional GSM internet module for data transmission via the GSM network
- Optional Solar Panel system
- Optional hull painting

WaveScan Buoy

The SEAWATCH WAVESCAN buoy (usually referred to as the WAVESCAN buoy, Fig. 6) is a versatile instrumentation platform that may be used in all applications. It has been designed to

Wave Measurement Buoy, Fig. 6 WaveScan buoy

provide less drag and large buoyancy, making it well suited for deep offshore locations or areas of strong current forces. The buoy's hull design is based on the dynamic response and stability requirements from comprehensive wave tank testing.

The WAVESCAN buoy is a multiparameter buoy that can be used to collect directional wave data as well as meteorological, oceanographic, and water quality parameters. The buoy also has innovative “wells” for sensor mounting, easing service, and maintenance.

Features

- The ideal buoy for deep water and severe current conditions
- A unique design optimizes wave direction measurements
- Multiparameter platform for client's chosen selection of sensors
- Modular shaped hull for easier transport and local assembly
- Real-time data transfer and presentation
- Full onboard processing of all measured data

Wave Measurement Buoy, Fig. 7 ODAS buoy

Wave Measurement Buoy, Fig. 8 Triaxys Directional Wave Buoy

- Two-way communication link for data transfer and control of a number of buoys
- Special mooring design minimizes mooring influence on buoy motions
- Successful track record worldwide since 198.

ODAS Buoy

An **ocean data acquisition system (ODAS, Fig. 7)** is a set of instruments deployed at sea to collect as much meteorological and oceanographic data as possible. With their sensors, these systems deliver data both on the state of the ocean itself and the surrounding lower atmosphere. The use of microelectronics and technologies with efficient energy consumption allows to increase the types and numbers of sensor deployed on a single device.

Triaxys Directional Wave Buoy

The TRIAXYS™ Directional Wave Buoy (AXYS Technologies, http://axystechnologies.com/products/triaxys-directional-wave-buoy/?open_cat=40, Fig. 8) is a precision instrument incorporating advanced technologies that make it an easy-to-use, reliable, and rugged buoy for accurate measurement of directional waves.

- The TRIAXYS™ sensor unit is comprised of three accelerometers, three rate gyros, a fluxgate compass, and the proprietary TRIAXYS™ Processor.
- The TRIAXYS™ provides continuous wave sampling, support for any telemetry, up to 10 Hz motion sampling and up to 32 GB (>5 years) of data logging capacity.
- The TRIAXYS™ sensor also uses the WatchMan500™ controller, which is the core

technology used in other AXYS monitoring systems.

- The TRIAXYS™ Directional Wave Buoy is solar powered.
- The TRIAXYS™ is easy to handle during deployment and can be rolled off a ship deck without any concern for sensor damage due to spinning.
- The TRIAXYS™ can also withstand extreme temperatures as its sensor is not subject to freezing.
- The TRIAXYS wave buoy can be configured with AIS Aid to Navigation to broadcast buoy position and weather information to local vessel traffic.
- TRIAXYS™ buoys have been deployed in waters from 10 to 300 m.
- Standard mooring configurations specially designed for wave buoys are available for water depths up to 300 m.

NOMAD Buoy

The AXYS NOMAD (AXYS Technologies, <http://axystechnologies.com/products/nomad-buoy/>) is a unique aluminum environmental monitoring buoy designed for deployments in extreme conditions. The NOMAD (Navy Oceanographic Meteorological Automatic Device) is a modified version of the 6 m hull originally designed in the 1940s for the US Navy's offshore data collection program. It has been operating in Canada's Weather Buoy network for over 25 years and commonly experiences winter storms and hurricanes with wave heights approaching 20 m.

- Custom configurable with a wide range of sensors for monitoring meteorological, oceanographic, and water quality parameters.
- A watertight central compartment houses the electronics payload, and there are two masts for mounting meteorological sensors, telemetry hardware, solar panels, and obstruction lights.
- Uses the WatchMan500™ controller to integrate sensor systems and provide onboard data processing, data logging, telemetry, and diagnostic/setup routines.
- A variety of telemetry options are available, including UHF/VHF, Inmarsat IsatData Pro,

Iridium, GPRS/HSPA, and CDMA/EVDO (Fig. 9).

Summary

There are many different types of wave measurement buoys deployed for measuring waves in oceans, and the principle for measuring waves is very similar. The choice of the wave buoys may be depending on many different requirements. For instance, in many applications, wave measurement may be only one of many other measurements: Small buoys are preferred if the wave measurement is the primary parameter and the shorter waves are more important while the large buoys provide more space and buoyance for accommodating more sensors for other measurements. Following table is a summary of the main buoys deployed in 2010 for measuring waves around the world (see Table 1).

Wave-Ice Interactions

Hongtao Li

Offshore Engineering Technology Center of China Classification Society, Tianjin, China
Sustainable Arctic Marine and Coastal Technology (SAMCoT), Centre for Research-based Innovation (CRI), Norwegian University of Science and Technology, Trondheim, Norway

Introduction

As a result of global climate change, it has been observed shrinking of ice extent and increase of

Wave-Ice Interactions, Fig. 1 Extent of sea ice in Arctic Ocean (National Snow and Ice Data Center 2018b)

wave height in the Arctic Ocean (Thomson and Rogers 2014; Vizcarra 2018). Figure 1 demonstrates the evident diminishing trend of Arctic Sea ice extent. Ocean waves were recorded even in the order of 100 km into ice cover (Liu and Mollo-Christensen 1988; Meylan et al. 2014). Large wave itself poses as a threat to human activities, such as natural resource exploration, shipping, and tourism. Similarly, structural damages of sea-going vessels and offshore structures because of severe ice condition have been documented. In addition to low temperature, combination of severe wave and ice conditions in Arctic Ocean makes the safe operation in this region challenging. Currently, the stage of modeling wave-ice-structure interaction has not been reached yet.

Wave-ice interactions are highly nonlinear and coupled. Waves accelerate the formation of ice in winter season, break ice, mobilize ice around, and bring heat by convection to speed up the melting of ice in warm weather. At the same time, ice refracts, scatters, damps waves, and changes wavelength.

Herein, we focus on the effects of ice on waves. To start with, a brief account of sea ice types and forming process is provided. Then, effects of ice on waves and wave-ice interaction theories are

presented. Lastly, this entry concludes with summary.

Growth of Sea Ice

Sea water freezes and forms sea ice. This process is different from how iceberg is produced. Iceberg originates from glacier. It should be noted that iceberg is of fresh water ice.

In the supercooled sea water, frazil ice firstly forms, which has needle-like crystals form (Rogers et al. 2016). Under the action of current and waves, these fine spicules are swept together to become oil-slick and matte looking grease ice (see Fig. 2a). Then, the evolution phase differs due to different sea states. Under calm sea, grease ice turns into nilas ice. This kind of ice responds to waves like elastic thin sheet that easily bends (Carsey 1992). Nilas ice may interlock with each other (namely, finger rafting, see Fig. 2b), because of the actions from currents or winds. More specifically, nilas ice interchangeably rides over and under each other (National Snow and Ice Data Center 2018c). Thereafter, nilas ice may thicken through rafting and freezing to form smooth continuous ice cover under calm sea.

Under slight to moderate sea, grease ice further aggregates to form pancake ice (see Fig. 2c, d), when the heat loss is sufficiently significant (Rogers et al. 2016; Wang and Shen 2010). The size of the pancake ice is governed by aggregation, bending, collision between ice and slope of sea surface (Shen et al. 2001). If the same environmental condition sustains, pancake ice cements between adjacent floes and thickens through rafting to form rough continuous ice cover (National Snow and Ice Data Center 2018a; Shen et al. 2001). If waves are strong, nilas ice may also evolve into rough continuous ice cover (Fig. 2e) by rafting and ridging. Sea ice growth process is summarized as shown in Fig. 3.

For a more detailed description of sea ice, readers are referred to Carsey (1992) for a summary of ice terminologies, Hobbs (2010) for physics of sea ice and Timco, and Weeks (2010) for engineering properties of sea ice. An old but still very valuable article is Weeks and Ackley (1986). Images of various ice types can be found in Fig. 8 of Lee et al. (2017), Antarctic Sea Ice Processes and Climate (2012), and PolarTREC (2018).

Wave-Ice Interactions

This section is divided into two subsections. Subsection “Effects of Ice on Waves” demonstrates various mechanisms to change properties of waves during wave-ice interactions. Subsection “Wave-Ice Interaction Models” gives an overview of different theories to model effects of ice on waves.

There have been several essential review literatures that summarize the knowledge in this field. Readers are advised to start with Li et al. (2018), Shen (2017), Zhao et al. (2015), and Collins et al. (2017). Hereafter, more comprehensive literature summaries, such as Squire et al. (1995) and Squire (2007), can be referred to.

Effects of Ice on Waves

To reveal how ice changes waves, Fig. 4 is provided to illustrate the various kinds of processes. This figure shows that a wave pattern, which consists of two harmonic waves (left panel of Fig. 4), attenuates when passing through an ice field. In this process, short waves are dissipated, and long waves with decreased amplitude retain (i.e., ice field acts as a low-pass filter, see the right

Wave-Ice Interactions, Fig. 6 Two models to describe viscoelasticity of ice

panel of Fig. 4). Various attenuation mechanisms, as shown in the middle panel of Fig. 4, contribute to this phenomenon.

Additionally, wave propagation direction alters because of refraction, reflecting and scattering in ice fields (Fig. 4f). Wavelength is modified as well due to the presence of ice.

Figure 5 depicts what wave period, wave amplitude, and wavelength represent, which of them are changed and associates with what processes.

Wave-Ice Interaction Models

The development of wave-ice interaction theories can be traced back to nineteenth century. Nevertheless, most of the research work commenced after 1950s. In what follows, typical theoretical models are presented.

Figure 6 depicts two commonly used rheological models, i.e., Kelvin-Voigt model (henceforth denoted as Voigt model) and Maxwell model that consist of spring and dashpots. These two models are often employed to describe the constitutive

relation of ice, i.e., relation between strain, strain rate and stress.

Table 1 summarizes the wave-ice interaction theoretical models used to quantify the change of wavelength and amplitude of waves when waves traveling into ice fields. In Table 1, the second column lists abbreviations of each model, and corresponding assumptions for ice and water are tabulated in the two columns that follow. Last column gives the criteria to choose physically meaningful solution results.

The forthcoming parts are based on the work of Li et al. (2018) and references cited therein.

Two common assumptions of these models are (1) ice layer always stays in contact with water; (2) small-amplitude and small-slope waves (i.e., linear wave theory). Because of linear wave assumption, these models only produce exponential decaying behavior of waves when waves propagating in ice fields. On the contrary, large waves in some regions of Arctic and Antarctic exhibited a different attenuation trend.

Regarding VSK, VSDD, and VCWS, in which ice layer is modeled as fluid, immiscibility is assumed between water and ice.

According to the fundamentals of these models, they can be classified into two groups: (1) physics-based model and (2) phenomenological model. GW model falls within the first category. This model is applied for each single ice floe in ice field and includes as many physic processes (such as scattering, reflection, and refraction) involved as possible. Other models belong to second group, where all dissipation mechanisms that contribute to waves damping are considered by one parameter – effective viscosity, and concrete physical processes are neglected. Implicitly, the whole ice field is viewed as a heterogeneous media. Hence,

Wave-Ice Interactions, Table 1 Wave-ice interaction models (Li et al. 2018 and references therein, reproduced with permission of Tatiana Uvarova)

Wave-ice interaction model		Ice	Water	Damping of wave energy by	Selected wave number (criteria)
Mass loading model	WK	Discrete mass point	Inviscid	Scattering	Two real (Geophysics relevant)
Thin plate model	GW	Thin elastic plate	Inviscid	Scattering	Two real (Geophysics relevant)
Viscous layer model	VSK	Viscous fluid layer	Inviscid	Viscous damping in ice	One complex (least damped wave mode)
	VSLM	Thin elastic plate	Viscous	Viscous damping in water	One complex
	VSDD	Viscous fluid layer	Viscous	Viscous damping in ice and water	One complex (closest to open-gravity wave with least attenuation)
Viscoelastic model	VCWS	Viscoelastic fluid layer (Voigt model)	Inviscid	Viscous damping in ice (linear dashpot)	One complex (closest to open-gravity wave with least attenuation)
	VCFS	Viscoelastic solid beam (Voigt model)	Inviscid	Viscous damping in ice (linear dashpot)	Two complex (in first quadrant of complex plane)
	VCRP	Thin elastic beam	Inviscid	Damping forces due to vertical velocity of beam	Two complex (in first quadrant of complex plane)
	VCM	Viscoelastic solid (Maxwell model)	Inviscid	Viscous damping in ice (nonlinear dashpot)	One complex (close to wave number of gravity wave)

these models are also called as effective media continuum models.

Conceptually, WK model is suitable for sparsely scattered small ice floes. Intuitively, GW model works well for pack ice. According to previous studies, VSK and VSDD model are more applicable for grease ice. VSLM model fits to be used for high concentration ice field. In contrast, VCFS and VCRP model are more suitable for sea regions that are sparsely populated by ice. In principle, VCWS should be suited for all above mentioned ice types.

Summary

This entry gives a concise illustration of growth of sea ice under the influence of waves. Moreover, mechanisms to change waves during wave-ice interaction are listed. Lastly, different wave-ice interaction models are presented. This work

contributes to easing the efforts of readers when reading pertinent literatures in this field.

Definition

Welding is the process of forming a permanent connection between two or more materials (of the same or different species) through the combination and diffusion of atoms or molecules. Compared with riveting, welding can save about 15–20% of metal materials. Compared with casting, the production of welding structure does not require the production of wood mold and sand mold, nor special smelting and casting equipment. The process is simple and the production cycle is short.

Welding is an important link in the construction of ships and marine structures (Wang et al. 2017). The quality and efficiency of welding directly affect the construction cost and quality of ships and marine structures. The development of welding technology is the basis for improving the construction level of ships and marine structures. In terms of shipbuilding technology, before the 1930s, most ship structures were riveted or bolted. Around the Second World War, welding technology began to be widely used in ship structures, and higher requirements have also been put forward for the weldability and welding technology of hull steel (Ma et al. 2017).

Welding Technology, Fig. 1 Welding robot

The development and application of welding mechanization and automation technology in shipbuilding and marine structures are very rapid. The technology of submerged arc welding and gas-shielded welding began to be applied in the 1950s, and the method of CO₂ gas-shielded welding began to be applied in the 1970s. At the same time, various types of automatic welding and semiautomatic welding methods were developed. In the 1990s, welding robot technology becomes more and more perfect and practical. Plasma arc welding, laser welding, laser-arc composite heat source welding, friction stir welding, and diffusion welding have been applied in the construction of ships and marine structures, which have greatly improved the welding precision and quality (Fig. 1).

Introduction

Welding Method

Arc welding is mainly used in the construction of ships and marine structures. Arc welding includes electrode arc welding, submerged arc welding, gas tungsten arc welding, gas metal-arc welding,

and plasma arc welding (Welding Society of Chinese Mechanical Engineering Society 2012). Their common characteristic is that the electric arc burning between the electrode and the workpiece serves as the heat source. When forming the joint, the filler metal can be used or not used.

Electrode arc welding is the earliest and still widely used arc welding method. It uses coated electrode as electrode and filler metal. The arc is burned at the end of the electrode and the surface of the welder. The coating can generate gas-shielded arc and weld under the action of arc heat, and the slag can be formed to cover the surface of the molten pool to prevent the interaction of molten metal from the surrounding gas. The more important function of slag is to produce physical chemical reaction with molten metal or add alloy elements to improve the performance of weld metal. Electrode arc welding equipment is simple, portable, and flexible. It can be used for repairing and welding short joints in assembly, and for welding hard-to-reach parts.

Submerged arc welding uses continuous feed wire as electrode and filler metal. When welding, a layer of granulated flux is covered over the weld zone, and the arc burns under the flux layer, melting the end part of the wire and the local base material to form the weld. Under the action of arc heat, part of the flux melts into slag and reacts with liquid metal. The slag floats on the surface of the metal pool. On the one hand, it can protect the weld metal, prevent air pollution, generate physical and chemical reaction with the molten metal, and improve the composition and performance of the weld metal. On the other hand, the weld metal can be cooled slowly. Submerged arc welding can use large welding current. Compared with electrode arc welding, its biggest advantage is good quality and high welding speed. Therefore, it is especially suitable for welding straight and circular joints of large workpieces, and most of them adopt mechanized welding.

Tungsten gas arc welding is a method of melting metal into weld by using the arc between tungsten electrode and workpiece. During the welding process, tungsten does not melt and only acts as an electrode. When welding, the inert gas argon or helium gas is used as the

Welding Technology,
Fig. 2 TIG welding gun

protective gas, and additional filler metal can be added as required, generally known as TIG welding. This method can control the heat input very well, so TIG welding is an excellent way to connect sheet metal and backing welding. The pulse form of welding current can better control the weld depth and improve the solidification characteristics of the weld pool. TIG welding can be used for almost all metal welding, including steel materials and nonferrous metals, and the weld quality is high, but compared with other arc welding methods, the welding speed is slow, and the thickness of the plates that can be welded is small (Fig. 2).

Gas Metal Arc Welding

In this method, the arc between the welding wire and the workpiece is used as the heat source, and the gas from the torch nozzle is used to protect the arc. Common shielding gases are argon, CO_2 , O_2 , or a mixture of these gases. When argon or helium gas is used as shielding gas, it is called metal inert gas arc welding (MIG welding). When CO_2 is used as a protective gas, it is called carbon dioxide gas-shielded welding. When mixed gas is used as a protective gas, it is called mixed gas arc welding.

The main advantage of arc welding is that it can be easily welded in various positions, and it also has the advantages of fast welding speed and high deposition rate. It is suitable for welding of most metals and arc spot welding.

In recent years, the requirements for welding precision and quality have been continuously improved. High-precision welding methods such as laser welding, laser-arc composite welding, and friction stir welding have also been applied in the construction of ships and marine structures (Farajkhah and Liu 2016) (Figs. 3 and 4).

High Heat Input Welding of Steel

In the process of welding, the heat circulation of welding will lead to the thick tissue around the welding seam. These areas with large grain size are called the welding-heat-affected zone. Grain coarsening in the heat-affected zone may lead to the decrease of toughness of welded joints. Compared with the base metal, the toughness loss in the heat-affected zone is generally 20–30% and can even reach 70–80% when serious. Although the width of the weld-heat-affected zone is only a few millimeters in general, the serious decline in

Welding Technology,
Fig. 3 Laser welding

Welding Technology,
Fig. 4 Friction stir welding

the toughness of the coarse crystal region in the heat-affected zone is likely to be the crack source, and the safety of the engineering structure cannot be guaranteed (Hamada et al. 1995).

In order to reduce the construction cost and improve the productivity of shipbuilding, shipbuilding enterprises widely adopt 100–500 kJ/cm high heat input welding and develop a series of hull steel for high heat input welding, such as YP355 steel developed in Japan in the early 1980s, and YP390 steel and YP47 steel developed in the mid-1990s.

The energy of welding line refers to the heat input amount of welding seam per unit length of time. The expression is: $E=IU/V$ (kJ/cm), where I (A) is welding current, U (V) is arc voltage, and V (cm/s) is welding speed. Generally, the welding energy greater than 50 kJ/cm in the welding process is called high heat input welding, such as single-side arc welding, gas-electric vertical welding, electroslag welding, etc.

Under the welding of high heat input, the microstructure of heat-affected zone of traditional low-alloy high-strength steel will grow rapidly, and the strength and toughness of the welding seam will also be significantly reduced, which is easy to generate welding cold cracks, bringing difficulties to the manufacture of large steel structures. At the same time, with the improvement of steel plate strength, its impact toughness and welding performance are significantly decreased, and the susceptibility of welding crack is increased, which makes it difficult to manufacture large steel structures (Yan et al. 2006).

The research and development of low-alloy high-strength steel for high heat input welding must take into full consideration the formation process and control method of the structure in the heat-affected zone. A large number of studies and explorations have been conducted on the characteristics of microstructure and properties of welded joints, microstructure transformation behavior, and the dynamics of austenite grain growth of low alloy and high strength steel, especially for the welding heat-affected zone of the acicular ferrite formation as well as the use of oxide metallurgy welding coarse-grained methods, to improve the toughness of a large

amount of basic research and applied research. The results show that there are many factors influencing austenite grain coarsening and toughness loss in the weld coarse crystal area. The alloy design, purity, metallurgical production process, precipitated phase type, and its composition, shape, size, and distribution of materials all have different effects. According to the above research results, some methods to improve the toughness of steel-heat-affected zone for large wire energy welding are put forward, which are mainly to reduce the carbon content, refine austenite grain by second phase particle precipitation, and promote the formation of acicular ferrite by using the principle of oxide metallurgy.

In order to improve the toughness of the heat-affected zone, a lot of research work has been carried out successively. The two main methods are reasonable composition design and oxide metallurgy (Wang et al. 2012).

Composition Design of Steel for High Heat Input Welding

At present, the basic idea of steel composition design for high heat input welding is to reduce the carbon content to ensure the weldability, increase the content of manganese and microalloyed elements, increase the strength, and control the content of impurities such as phosphorus and sulfur. The oxide metallurgy method is adopted to form small dispersed fine inclusions, which can inhibit the austenite body length and control tissue transformation in the welding process, and keep the toughness of the steel coarse crystal area for high heat input welding at a good level.

Oxide Metallurgy Technology

Grain refinement is an effective way to improve the toughness. The smaller the grain size of the heat-affected zone, the better the toughness. In 1990, researchers at Nippon steel, Japan, first proposed the concept of oxide metallurgy, which controls the composition of oxides and makes them small and dispersed. The size, shape, and distribution of sulfide, carbonitride, and other nonmetallic inclusions are controlled by controlling the small, dispersed, high solubility

microinclusion material points in the molten steel. On the one hand, these inclusions prevent austenite grains from growing in the heat cycle of welding. On the other hand, they promote the nucleation of acicular ferrite, so as to refine the fine inclusions in the high heat input welding effectively and improve the toughness of the heat-affected zone. A large number of studies have shown that it is a very effective way to improve the toughness of heat-affected zone by utilizing the fine inclusions in these steels. Oxide metallurgy technology provides a new way of thinking for the development of high heat input welding steel.

Welding Deformation and Residual Stress

Welding deformation and residual stress are common problems in the welding of ships and marine structures, which have important influence on welding precision and welding quality.

The fundamental reason of stress and deformation during welding is that the welding parts are heated unevenly, and the thermal deformation and tissue deformation caused by heating are restrained by the rigidity of the welding parts themselves (Fang 2017). The stress and deformation occurring in the process of welding is called transient stress deformation, while the residual stress and deformation after the completion of welding and the complete cooling of components are called residual stress and deformation. The residual stress and deformation of welding seriously affect the bearing capacity and service life of welding structures (Chen et al. 2015).

During welding, the weldment is heated unevenly and the weld zone melts, while the thermal expansion of the high-temperature zone material adjacent to the welding pool is restricted by the surrounding cold state material, resulting in uneven compressive plastic deformation. During the cooling process, this part of the material (such as the two sides of the long weld) that has undergone compressive plastic deformation is also restricted by the surrounding metal and cannot freely contract, and to a certain extent, it is unloaded by stretching. At the same time, the weld pool solidifies and the weld metal cooling shrinkage is restricted, resulting in shrinkage

tensile stress and deformation. Thus, a shortened uncoordinated strain, called residual strain, or initial strain or inherent strain, is generated in the welded joint area.

Welding stress and deformation are caused by the interaction of many factors. The local uneven heat input during welding is the decisive factor for the formation of welding stress and deformation, and the heat input influences the metal movement around the heat source through the internal and external constraints formed by material factors, manufacturing factors, and structural factors, and finally forms the welding stress and deformation. The internal constraint of metal motion around the heat source mainly depends on the thermal physical parameters and mechanical properties of the material, while the external constraint mainly depends on the manufacturing and structural factors.

The basic law of welding stress and deformation is consistent with that caused by deformation and uneven temperature, but the process is more complicated. The main performance is that the temperature change range is larger when welding, the highest temperature on the weld can reach the boiling point of the material, and the temperature drops sharply from the welding heat source to the room temperature.

The appearance of welding deformation will bring a series of problems (Wang et al. 2018). Once the welding structure is deformed, it often needs to be corrected and is time-consuming. Sometimes, the more complex deformation correction workload may be greater than the welding work, and sometimes, the deformation is too large, may not be able to correct, resulting in waste. For the workpiece that needs to be machined after welding, the deformation increases the machine load and material consumption. The appearance of welding deformation will also affect the beauty and dimension precision of components and may reduce the bearing capacity of structures and cause accidents.

The control methods of welding deformation mainly include rigid fixation method, reverse deformation method, reasonable welding sequence selection, and reserved shrinkage allowance method.

Rigid Fixation Method

The method of reducing welding deformation by using external rigid constraint is called rigid fixation method. When assembling the plate, fixing the spliced steel plate on the platform with positioning welding can reduce the wave deformation of the steel plate. To prevent corner deformation, two end plates can be welded at both ends of the joint. In the process of hull construction, several process reinforcing plates are often welded along the joint weld to prevent angular deformation. When applying rigid fixation method, it is necessary to pay attention that the binding effect of the fixture will inevitably increase the welding stress and the possibility of welding crack. Therefore, this method is often used in welded steel structures, but not for cast iron and some high strength steel.

Inverse Deformation Method

Before welding, the deformation size and direction of the structure are estimated in advance, and the component is installed into a deformation in the opposite direction to offset the deformation caused by the welding process. This method is called reverse deformation method. This method is often used in the construction of ships and marine structures.

Select Reasonable Welding Sequence

In the process of assembly and welding, the influence on deformation is complicated due to the large number of welding seams. In order to control the deformation, the structure is divided into several parts, assembled and welded respectively, and then the welded parts are assembled into a whole. This allows asymmetrical or larger welds to contract freely without affecting the overall structure.

Reserve Shrinkage Allowance Method

The shortening of the longitudinal (along the weld direction) and transverse (perpendicular to the weld direction) of the component after welding can be controlled by estimating the weld shrinkage and leaving the shrinkage allowance in advance during the material preparation process.

The characteristics of welding residual stress include (Gadallah et al. 2017):

1. Mutual balance. Internal stress, tensile stress, and compressive stress coexist.
2. Follow the principle of stress superposition. The working stress caused by the load can be superimposed with the welding residual stress when the unrelieved stress is used.
3. A phenomenon of stress redistribution. When the stress and residual stress caused by external factors of the welded parts are superimposed, the ductile deformation will occur in this area when the yield point of the base metal is exceeded.
4. Without the occurrence of welding deformation, there is no obvious appearance. After a large number of welding, the appearance may not change, but there is a great stress in the interior.

The existence of welding residual stress has the following effects on the safety and service performance of welded joints and even welded structures:

Effect on Structural Rigidity

When the stress generated by the external load and the residual stress in a certain area of the structure are superimposed to reach the yield point of the material, the material in this area will undergo plastic deformation and further lose the ability to withstand the external load, resulting in the reduction of the effective section area of the structure and the decrease of the stiffness of the structure. When the external load is in the same direction as the longitudinal residual stress, the deformation is greater than that without residual stress. When unloading, the strain relaxation is less than the deformation when loading, and the component cannot be restored to the original size. The larger the tensile stress area in the component, the greater the impact on the stiffness and the greater the residual deformation after unloading.

Effect on Stability of Compression Bar Parts

When the compressive stress caused by the external load and the compressive stress component in the residual stress are superimposed to reach the yield point of the material, this section loses the ability to bear the compressive stress load further.

In this way, the effective cross-sectional area distribution of the bar is weakened, and the stability of the bar is changed.

Effect on Static Load Strength and Brittle Fracture

When there is a serious stress concentration and a high residual stress in the actual component, and if the working temperature is lower than the critical temperature of brittleness, under the combined action of tensile stress and working stress, the static load strength of the structure will be reduced and brittle fracture will occur under the action of the external load stress far below the yield point.

Effect on Fatigue Strength

The existence of residual stress makes the stress cycling average of cyclic load deviate, but does not affect its amplitude. As the mean value of the stress cycle increases, its limit decreases, otherwise it increases. Therefore, if there is stress concentration and residual stress, the fatigue strength will decrease. If the residual stress is eliminated under the external load, the residual stress will be weakened. The higher the stress concentration coefficient, more obvious the influence of residual stress.

Effect on Stress Corrosion Cracking

Stress corrosion cracking is a phenomenon of cracking of structures under the action of low stress in a certain environment. When material and medium match, the time required to produce stress corrosion cracking is inversely proportional to the stress. The greater the tensile stress, the shorter the time of stress corrosion cracking. Stress corrosion cracking can be avoided if residual compressive stress layer can be created on the surface of components that contact with corrosion media.

The Influence on Welding Precision and Dimension Stability

For the component with residual stress, if the original residual stress field is damaged during machining, and the residual stress can be released or redistributed, the component will be deformed and the machining accuracy will be affected. After the component with residual

stress is placed for a period of time, the stress relaxation will occur due to aging effect or unstable tissue, leading to the instability of structure size. When the temperature rises, the relaxation will increase significantly and the material with unstable tissue is produced after welding. As the unstable tissue changes over time, the residual stress changes greatly, and the dimension stability of the welded parts is poor.

Fatigue Strength of Welded Joints

The marine engineering structure is affected by wind, wave, and flow, and the sensitivity of high strength steel to stress concentration is higher than that of low carbon steel. Therefore, the fatigue strength of ocean engineering welding structure must be considered (Yan et al. 2016).

Factors affecting fatigue strength of metallic materials (such as stress concentration, section size, surface state and load conditions, the application environment, etc.) also have influence on the fatigue strength of welded structure (Sankaran and Sarma 2003). In addition, some characteristics of the welding structure itself, such as the change of properties of area near weld zone in the joint, welding residual stress, and so on, could also affect fatigue strength of welded structure (Chapatti et al. 2003).

The main technological measures to improve the fatigue strength of welding structures are:

Specific measures to reduce stress concentration include:

1. Using reasonable structural forms to reduce stress concentration in order to improve fatigue strength.
2. Adopting the welding joint forms with small stress concentration coefficient possibly, such as butt joint.
3. Comprehensive measures should be taken to improve the fatigue strength of joints when fillet welds are adopted (machining the end of the weld seam mechanically, selecting the shape of the joint of plates reasonably, ensuring the penetration of the weld root, etc.).
4. Using surface machining to eliminate various grooves in the weld and its vicinity can reduce the stress concentration in the components to improve the fatigue strength.

5. Adopting TIG arc or plasma beam-shaping method instead of mechanical processing to make a smooth transition between the weld seam and the base material.

Adjust the Residual Stress Field

The fatigue strength of the joint can be improved by eliminating the residual tensile stress at the stress concentration or producing the residual compressive stress here. This method can be divided into two types: One is structural integral treatment, such as integral annealing or overloading prestretching; the other is the local treatment of the joint, such as heating, rolling, and local explosion of a part of the joint so that the residual compressive stress is generated at the stress concentration of the joint.

Improve the Surface Properties of Materials

The fatigue strength of the joint can be improved by surface-strengthening treatment, extrusion with small wheels, tapping the weld surface and transition zone lightly with hammer, or spraying the weld zone with small steel balls.

Special Protective Measures

The fatigue strength of materials is often affected by the medium, so it is beneficial to apply notched surface coating.

Requirement of Marine Engineering Structure for Weld Seam

The butt weld of marine engineering structure should be fully welded. The shape of the remaining height of the weld should meet the requirements, and be smoothly transferred to the base material.

Fillet welds are usually used for the connection between plates and stiffeners, the fixation of bracket plates, etc. If there is an allowable assembly gap between welds, the weld thickness should be increased accordingly.

The important fillet welds, as well as those of strong stress components which may cause fatigue, should be fully welded. The technological measures such as alternating symmetric welding and presurfacing weld bead on groove surface can be adopted when welding (Calle and Alves 2015).

Reasonable assembly steps and welding sequence are adopted to control the deformation

caused by the weld to avoid excessive residual stress and crack (Zhao et al. 2017).

For the joints of thick components and pipes:

1. Low-hydrogen electrode and reasonable welding technology should be adopted to ensure complete penetration.
2. Preheating should be done before welding, and postwelding heat treatment should be done according to the regulations after welding.
3. The pipe joints shall not be burnt through during welding, the weld surfaces shall be continuous and even, and the joint between the two pipes shall gradually make a smooth transition. It is recommended to use small diameter electrodes for cover welding to improve the fatigue properties of joints. If the project requires polishing the joint of the pipes, the radius of curvature of the surface of the weld seam after grinding shall comply with the relevant design and manufacture regulations.

Winch

Liping Sun

College of Shipbuilding and Ocean Engineering,
Harbin Engineering University, Harbin,
Heilongjiang, China

Definition

Winch is a mechanical device that is used to pull in (wind up) or let out (wind out) or otherwise adjust the tension of a rope or wire rope (also called “cable” or “wire cable”).

Scientific Fundamentals

Historical Development

The earliest literary reference to a winch can be found in the account of Herodotus of Halicarnassus on the Persian Wars (Histories 7.36), where he describes how wooden winches were used to tighten the cables for a pontoon bridge across the Hellespont in 480 B.C. Winches may have been employed even earlier in Assyria. By the fourth

century BC, winch and pulley hoists were regarded by Aristotle as common for architectural use (Coulton 1974).

The yacht *Reliance*, American defender of the 1903 America’s Cup, was the first racing boat to be fitted with modern winches below decks, in an era when her competitors relied on pulley systems (block and tackle).

In its simplest form, it consists of a spool and attached hand crank. In larger forms, winches stand at the heart of machines as diverse as tow trucks, steam shovels, and elevators. The spool can also be called the winch drum. More elaborate designs have gear assemblies and can be powered by electric, hydraulic, pneumatic, or internal combustion drives. Some may include a solenoid brake and/or a mechanical brake or ratchet and pawl device that prevents it from unwinding unless the pawl is retracted (Smith 1999) (Fig. 1).

Marine winch is an important lifting and pulling equipment used on boat/ship, on the dock or shore, in the port, on offshore platforms, etc. for anchoring, mooring, towing and weights lifting, or pulling, and there is also subsea winch used for some submarine operations. The main structures of marine windlass comprise drum, gypsy wheel, chain, cable, manual band brake, manual clutch, power system and control system, etc. In addition to drum, many winches have one or two small warping heads. Take marine drum winch, for example, it can have one or two drums with or without warping head. Clients can customize by their needs. Speaking of the commonly

Winch, Fig. 1 The form of winch (<http://cn.bing.com/>)

used marine winches, they can be anchor winch, anchor and mooring winch, towing/tugger winch, mooring winch, combined windlass like electric single drum combined winch and electric double drum combined winch, and so on (Blanc et al. 2006).

Ship winch refers to the winch mounted and used on a ship and it is a necessary deck equipment for the ship, which can be used for ship anchoring, mooring, towing, cargo lifting and cable pulling, and so on. According to drum quantity, there is single drum ship winch, double drum ship winch, and triple drum ship winch; the drum brake device should be able to withstand the winch support load, and it should not rotate after braking. According to drive type, ship winch includes electric ship winch, hydraulic ship winch, electric-hydraulic winch, diesel winch, steam winch, and manual winch; according to the type of drums, the winch drums can be split or undivided as needed; as for the brake type and brake application, there are mainly band, disc, mechanical screw, and spring applied. The main specifications of hydraulic winch consist of rated

load, support load, rope speed, rope capacity, power mode, etc.

Ship winches are very useful whenever the ships need to be anchored, stopped, towed, or there are something on ships needed to be lifted or pulled. When a ship reaches a port or pier, it needs to stop, and the ship anchor and mooring winch will be used to help with the ship anchoring and mooring to make sure it stops and keeps in the place safely without moving or drifting; according to ships with different sizes, shapes, and rope capacities, they will choose windlasses with different rated loads and drums; when the ship starts to set sail after the stop, the winch will let in the line attached to the anchor to make the ship leave the port or pier; when a ship needs to be towed under some special circumstances, the winch will connect the ship to the tug boat to implement the towing operations; when there are some loading and unloading operations on ship, the winch will also be used to finish the weights lifting work (Blanc et al. 2006) (Fig. 2).

The most common use of winches on ships is for mooring, which means the winches are

Winch, Fig. 2 Ship winch

usually located on the fore and after the decks at both sides of the ships. The mooring system can hold a ship in position and prevents the ship from drifting away from a berth. The ship mooring winch performs variety of functions, for example, the winch serves to store the mooring line when it is not in use, to haul the ship in place against environmental forces, or it can also act as a kind of safety device which releases the line load in a controlled way once the force in the mooring line increases to the limit of breakage (Chakrabarti 2005).

Mooring winch is the mechanical equipment used by ships to dock at docks; tie-up pontoons, alongside ships; to enter and leave docks; etc. It is commonly called mooring equipment.

Mooring winch is mainly composed of mooring lines, mooring piles, cable guide holes, winch, rope wagons, collision pads, etc. The ship can be moored by using a stranding machine to take up the stranding cable. At the bow, the mooring reel is usually driven by the same power as the windlass and can also be engaged or disengaged by clutches.

The type of winching equipment required in a particular mooring system depends on the type of mooring line to be handled and whether or not the floating vessel itself must initially tension the mooring lines or test load anchors. A floating vessel often has the means of adjusting mooring line tension, retensioning after anchor drag, and disconnecting individual mooring lines.

Main Types and Working Principles

There are two types of winch: normal type and automatic tensioning type (Smith 1999).

The composition of the normal type winch is similar to that of the windlass, and it can also share a set of driving device with the windlass. Its function is to tighten the cable and tie it to the cable pile. While the automatic tensioning cable winch is provided with a cable winding drum, the cable is wound on the cable winding drum, has a separate driving power, and automatically tightens or releases the cable by taking the tensile force of the cable as a signal, so as to adapt to the influence of tide level and cargo loading and unloading on the ship, and is beneficial to

reducing the labor intensity of the crew. However, one winch can only hold one rope by itself, so the number of mooring winch need more.

The working principle of the automatic tensioning hydraulic cable winch is: when the tension on the cable increases, the pressure of the hydraulic system increases, and when the pressure is greater than the setting value of the constant tension valve, the valve opens, allowing the inlet and outlet of the hydraulic motor to communicate. Under the action of the tension of the cable, the hydraulic motor rotates to release the cable, the tension decreases after the cable is released, and the constant tension valve closes. When the tensioning force on the cable is reduced, the hydraulic pump supplies oil to the hydraulic motor so that the hydraulic motor rotates to tighten the cable in the cable direction. When the pulling force on the cable is balanced with the set value of the constant tension valve, the oil supply of the hydraulic pump bypasses through the constant tension valve. In order to reduce the loss of hydraulic energy, large and small hydraulic pumps are permanently installed in the hydraulic system of the automatic tensioning cable winch. The large pumps are used in normal cable collection and discharge conditions. The small pump is used for automatic tensioning.

The load capacity, rope capacity, rope diameter, rated speed, and dimension of the winch vary according to different needs and conditions; they are in the different ranges and can be customized. A marine winch is a piece of marine deck equipment applied for handling ropes or wires, and works by spooling or winding the ropes or wires on a drum with a horizontal axis. Powered by electric or hydraulic motors, the winches on ship are fixed and used for various purposes.

The winch can also be divided into the following four types according to the material and characteristic of mooring lines.

Windlass

The most common method of handling and tensioning chain is through the use of a windlass. The windlass consists of a slotted "wildcat" which is driven by a power source through a gear-

reduction system. As the wildcat rotates, the chain meshes with the wildcat is drawn over the top of the wildcat and lowered into the chain locker. Once the chain is hauled in and tensioned, a chain stopper or brake is engaged to hold the chain. Windlass has proven to be a fast and reliable method for handling and tensioning chain (Luo et al. 2015) (Fig. 3).

Chain Jack

Chain jack is a device which reciprocates linearly to haul-in and tension chain. Usually powered by one or more hydraulic cylinders, chain jack engages the chain, pulls in a short amount of the chain, engages a stop, retracts, and repeats the process. Although chain jack can be a powerful means for tensioning chain, it is very slow and is recommended for applications not requiring frequent line manipulation (Luo et al. 2015).

Drum-Type Winch

Conventional drum-type winch is the most common method used for handling wire rope. Operation of drum-type winch is fast and smooth. - Drum-type winch consists of a large drum on which the wire rope is wrapped. The base of the drum is often fitted with special grooves sized specifically to the size of wire rope being handled. The groves control the positioning of the bottom layer of wire rope on the drum. For subsequent layers of wire rope, an external guidance mechanism such as a level-wind is often used to control positioning of the wire rope on the drum. The tensioning capacity of the winch is a function of number of wraps on the drum.

Drum-type winch can be a cumbersome method of handling wire rope for deepwater or high strength mooring systems. As the requirement for line sizes and lengths increases, the size

Winch, Fig. 3 Windlass

Winch, Fig. 4 Drum-type winch

of the winch can become impractical. In addition, when wire rope is under tension at an outer layer on the drum, spreading of preceding layers can occur causing damage to the wire rope (Luo et al. 2015) (Fig. 4).

Linear Winch

Linear winch is similar in principal to chain jack. Two sets of grippers, one stationary and one translating, are used to haul-in and tension the wire rope. Linear winch is available in a single-acting form, in which the wire rope moves intermittently as the gripper is retracted to begin another stroke, and in a continuous double-acting form, two translating grippers are used alternately for continuous smooth motion of the wire rope. Linear winch is most applicable in a permanent application when high tension and large-diameter wire rope is required. A take-up reel is necessary in this case to coil the wire rope after it passes through the linear winch (Luo et al. 2015).

Traction Winch

Traction winch has been developed for high tension mooring applications as well as for

handling combination mooring systems. It consists of two closely spaced parallel mounted powered drums, which are typically grooved. The wire rope makes several wraps (typically 6–8) around the parallel drum assembly. The friction between the wire rope and the drums provides the gripping force for the wire rope. The wire rope is coiled on a take-up reel which is required to maintain a nominal level of tension in the wire rope (typically 3–5% of working tension) to ensure the proper level of friction is maintained between the wire rope and the traction winch. This system has been favored for use in high tension applications due to the compact size, capability to provide constant torque, and ability to handle very long wire rope without reduced pull capacity.

Key Applications

The rope may be stored on the winch. When trimming a line on a sailboat, the crew member turns the winch handle with one hand, while tailing (pulling on the loose tail end) with the other to maintain tension on the turns. Some

winches have a “stripper” or cleat to maintain tension. These are known as “self-tailing” winches.

Winches are frequently used as elements of backstage mechanics to move scenery in large theatrical productions. They are often embedded in the stage floor and used to move large-set pieces on and off.

Off-road vehicles often carry a winch which may be electrically or hydraulically powered and is wound with rope or a wire cable. If the vehicle loses traction, the winch is used to pull it back to firmer ground.

The purpose of windlass/winch is to control the speed of chain (cable) movement when releasing and recovering, and pre-tightening and adjusting the tension of chain (cable) while anchoring.

There are some requirements for winch design (Piggott 1977):

1. To ensure that the ship can still tie up when it is subjected to wind force below level 6.
2. The tensile force of the winch shall conform to the requirements of “code for the classification and construction of steel sea-going ships.
3. The wringing speed is usually 15~30 m/min, with a maximum of 50 m/min. When the rated pulling force is reached, it can be reduced to the minimum.

Definition

Wind tunnel tests are tests performed in a tunnel with aircrafts, including wing-in-ground-effect ships, other surface ships, offshore structure models, or submarine and submersible models in different speed artificial air flow, which are the most popular tests in aerodynamic and hydrodynamic research. As the similarity between water and air, wind tunnels are also useful and important tools compared with towing tanks (<https://www.en.wikipedia.org/wiki/windtunneltests>).

Scientific Fundamentals

Wind Tunnel Types

Different types of wind tunnels can be divided by the top wind speed in the tunnel. These include low-speed wind tunnel, subsonic wind tunnel, transonic wind tunnel, supersonic wind tunnel, and hypersonic wind tunnel (Korsmeyer 1996). A division of various wind tunnels is given in Fig. 1.

The wind speed in the tunnel is V , and the speed of sound in the air is c , then the Mach number can be defined by the formula, $Ma = V/c$.

- Low-speed wind tunnel, $Ma < 0.3$. The air density keeps the same when as its speed is zero.
- Subsonic wind tunnel, $0.3 < Ma < 0.8$. The air density becomes different.
- Transonic wind tunnel, $0.8 < Ma < 1.2$.
- Supersonic wind tunnel, $1.2 < Ma < 5$.
- Hypersonic wind tunnel, $Ma \geq 5$.

Submersible or submarine models can be installed in wind tunnel and resistance measurement or flow-field measurement can be carried out. Usually the low-speed wind tunnel is suitable for their tests.

Wind Tunnel Test Types

A division of various wind tunnel tests is given in Fig. 2.

These include force measurement, pressure measurement, heat conduction tests, and flow-field observation.

- Force measurement tests are the basic wind tunnel tests. The resistance, trimming moment, lifting force, and so on can be measured of the model.
- Pressure measurement tests are important when people want to know the pressure distribution on surface of the model.
- Heat conduction tests are usually for high speed or super high-speed vessels. As the speed increases, the friction between the air flow and vessels become larger. When it is supersonic or even hypersonic, the heat is large enough to burn the vessel to ashes.
- Flow-field observation is usually carried out by using smoke or wires, which will show the direction of the air flow. Nowadays, new technologies such as particle image velocimetry are applied since the 1980s.

Historical Development

It is believed that the first wind tunnel in the world was built in 1871 by the British. The Wright Brothers built a wind tunnel in 1901 in order to carry out different tests for their aircraft model, whose section area was 0.56 m^2 and top wind speed was 12 m/s . With the help of the wind

Wind Tunnel Test,
Fig. 1 A division of
various wind tunnels

Wind Tunnel Test,

Fig. 2 A division of various wind tunnel tests

Wind Tunnel Test, Fig. 3 The Jiaolong sub model in wind tunnel

tunnel their plane flew in the sky 2 years later, which was believed the first plane in the world.

In the middle of the last century, wind tunnel tests became widely used by not only aircrafts manufacturers but other company, for example, the car industry. In the 1920s, Jaray started to do wind tunnel tests for cars. He did a good job to decrease the wind resistance of cars by carrying out a lot of wind tunnel tests. The aerodynamic drag takes more than 30% of the total resistance when a car drives at 180 km/h. After World War II, vessel engineers built hundreds of wind tunnels and have made great efforts to reduce the aerodynamic drag by more than 60% (Quix 2015; Forte 2012).

Scientists found that aerodynamic and hydrodynamic flow were always based on the same laws, which became the theoretical basis that ship and submarine model tests were widely carried out in wind tunnels. The hydrodynamic

coefficients of submarines or other under water vessels are studied.

During the design of the 7000 m deep manned Submersible “Jiaolong,” lots of wind tunnel tests were carried out (see Fig. 3). Different design was compared for better performance and higher safety.

Key Technology in Carrying Out a Wind Tunnel Test

There are four elements for successful wind tunnel tests. They are the wind tunnel and fans, the model, measurement device, and model vibrations.

1. The wind tunnel and fans

The wind tunnel should be large enough for the model. The cross-sectional area of models should be less than 5% of the wind tunnel.

The artificial aero flow produce by fans in wind tunnel should be fairly well distributed and stable for both the time dimension and space dimension.

As there is a lot of noise when the fans are working, it is suggested to build the wind tunnels far from living area.

2. The model

The model ship and the full-scale ship are geometrically similar. The model should be manufactured with high precision. And there are rudders or fins, which should be manufactured and installed to the model. Sometimes they are too small to be well manufactured. In other cases, manipulators, for example, are usually too complex to be manufactured. The model is simplified in most cases (Owens 2011). How to simplify the model should be recorded. Turbulence stimulators are usually installed on the model as the Reynold Number is not high enough to make the laminar flow turn to turbulence flow.

And the roughness of the model skin should be carefully paid attention to. Usually the models are painted with some standard methods.

3. Measurement device

Measurement devices are usually divided into three kinds, including force measurement balances, pressure and speed measurement sensors, and aero flow visualization devices. Five- or six-component testing system and the methods for resolving calibrating matrix are proposed in wind tunnel tests. Pressure sensors are developed to capture the high-frequency fluctuation aero flow. Particle image velocimetry technologies are widely applied in recent decades as flow visualization methods. Smoke and thin wires are the traditional and classical methods (Brooks 2014).

4. Model vibrations

During wind tunnel tests, aero turbulence, model structure, and aerodynamic forces will make the model vibrate with a high frequency. Model vibrations affect the measurement and the model tests cannot carry out in some cases. Model vibrations should be restrained and controlled.

Winterization of Polar Engineering

Lei Ju and Yongkui Wang
College of Shipbuilding Engineering, Harbin Engineering University, Harbin, China

Synonyms

[Antifreeze of the polar ocean platform](#); [Polar Engineering antifreeze](#)

Definition

The polar offshore platform is the carrier of resource exploration, development, transportation, and scientific research activities in polar regions. However, the polar climate is extremely harsh, and the temperature is very low over the years. The Polar Engineering antifreeze is a technology that ensures the safe and efficient operation of the offshore platform in a complex and abominable low-temperature polar region and

provides a more comfortable working life environment for the staff.

Scientific Fundamentals

Polar Low-Temperature Environment

In the Arctic region, the winter time is long, the temperature is between -43°C and -26°C , the average temperature is -34°C , the air sea air exchange is strong and the humidity is very high, and the relative humidity is above 95% for most of the time, which shows the fog and thick fog. The ice overlying under the extreme climate has a great influence on the polar ocean platform (Horjen 1989).

According to the guidelines for the polar ships issued by the China Classification Society, the polar vessels operating at low temperature or season should take into account the exposure to the ambient temperature of the structure, equipment, and the surface of the system and take appropriate measures of protection or operation control to ensure that the ship and equipment have operational capability in the polar service temperature environment (China Classification Society 2016).

Ice Cause, Harm, and Ice Zone Specification

Cause of Icing

There are two main reasons for ice formation on the offshore platforms, namely, meteorology and ocean spray. The former is a secondary cause and the latter is the main reason.

The meteorological conditions mainly include snow, freezing rain, fog and hail, and so on. The overcooled droplets in the atmosphere form a large amount of icing on the surface of the structure, such as the icing on the cable, the lifesaving equipment, the air vent, and so on (Xie et al. 2017). When the temperature is less than or equal to 0°C , freezing rain will cause obvious ice formation on the platform surface. Freezing fog can also cause ice. The amount of ice generated by freezing fog is usually small, but if the duration of the fog is longer, it may cause an increase in ice accretion. Snow will cause icing

on the horizontal structure of the platform, such as deck.

The droplet is caused by the impact of the ocean wave platform. Due to the lower seawater temperature and air temperature, the droplet adheres to the hull, and the heat dissipated rapidly, resulting in ice formation. The conditions for ice spray formation are as follows: the air temperature is below -2°C , the wind speed is greater than 16 knots, and the surface seawater temperature is -1.8°C ~ -6.0°C (Yang 2015).

Icing Damage

Polar ice platforms can reach hundreds of tons of ice and may encounter the following phenomena and hazards when operating in low-temperature environments:

1. Ice will affect the platform body, the wet gas condensation, and freezing of the cold surface of deck and cargo equipment, and the splash water and rainwater on the superstructure of the platform are frozen on the exposed surface, which will reduce the stability of the platform. For floating platforms, the weight of icing will increase the heeling moment and reduce the freeboard height (Wold 2014). Ice formation will not only affect the floatability and stability of the platform but also increase the wind area of the platform and increase the wind overturning moment, which may lead to the overturning of the platform.
2. Icing can cause damage to the equipment in the polar working area, such as freezing winches, cranes, valves, covering windows, blocking air outlets, etc. Low temperature will affect the material properties of the platform structure, increase brittleness and thermal expansion, reduce allowable stress and structural reliability, and damage the equipment when used. The windows of the vents are mostly designed with mesh and lattice, which are easy to be covered with ice and snow plugging, which will bring problems to the health and mechanical operation of personnel. The lunar pool is an open area located in the center of the offshore platform; the drilling equipment is operated in this area. The icing will cause the valve to be

unable to work and the efficiency to be low (Xie et al. 2017). Icing may affect deck operation of platforms, such as the possibility that lifeboats/lifesaving valves can't be released properly.

3. Ice can affect the safety of the platform. Salt-water is likely to freeze on the antenna, GPS, radar, and other equipment, affecting the normal work of these devices (Gauthier et al. 1997). If the ice covers the cab windows, it will affect the operator's line of sight. Ice in the open deck passage of the platform will cause difficulties for the crew to walk. If the ice fall off the superstructure, it will directly threaten the personal safety of the crew (Xue 2013). Icing can reduce the self-rescue capacity of the offshore platform, such as covering fire extinguishing equipment, freezing fire extinguishing water gun valves, and blocking smoke sensors, all of which have a great impact on the safety of the platform.

Ice Zone Specification

In the 1930s, Finland and Swedish Maritime Administration first standardized the ice area enhancement of ships in the Finland-Swedish Ice Class Rules (FSICR). The polar classification requirements issued by the International Association of Classification Societies, including ten major classification societies including China Classification Society, were formally promulgated in 2006, and the hull structure was modified in 2010. In addition, Det Norske Veritas (DNV) also adds the WINTERIZATION entry symbol, which mainly considers the design requirements of the platform for the short-term working in the extremely cold environment and does not consider the ice in the surface. The aim is to ensure that the system and equipment can work properly in the design temperature range and reduce the threat of cold environment to operators (Det Norske Veritas 2008).

DNV has the following requirements for ocean engineering projects:

1. In ship or ocean engineering projects of the WINTERIZATION entry symbol, the calculation of space heating heat balance must assume

that the ambient temperature of the space is -30°C .

2. Heating power requirements for antifreeze and deicing are required: The open deck, helicopter deck, access, and staircase are not less than 300 W/M^2 ; the superstructure is not less than 200 W/M^2 ; the handrail is not less than 50 W/M^2 .

Antifreeze Design

The icing on the polar offshore platforms is mainly caused by seawater splashing. The effective ice protection and deicing design can significantly reduce the ice coverage. Polar antifreeze technology mainly includes five aspects: platform structure design, regional protection, selection of outdoor equipment, heat supply system heating, and coating protection. Polar offshore platforms can be designed frostproof from these five aspects:

Platform Structure Design

For the offshore platform, it is possible to design the pile foundation of the platform into large diameter and to make the bottom of the deck more flat to increase the possibility of the ice layer to fall off through its own gravity, in order to effectively reduce the amount of water splashing ice. Increasing the design of smooth surface and vertical surface and reducing the number of small components can reduce the mechanical interlocking of icing and equipment and improve the convenience of deicing and the possibility of icing and falling off.

Antifreeze Design in Open Area

The antifreeze design in the open area mainly includes the layout of the windbreak wall, the calculation of the heat load in the antifreeze room, the design of the electric tracing system, and the piping layout.

When the offshore platform works in the harsh environment, the deck platform is easy to freeze. It will not only affect the normal work of the equipment but also affect the operation of the crew, so the installation of the protective wall can greatly improve the working conditions. Considering the function of the equipment, the

platform can install a windbreak for some parts of the open deck machinery. The main equipment for installing the windproof wall is as follows: installation of windproof walls around the main deck, installation of windbreak storehouse in drilling pipe/drilling riser area, lifeboat/salvage yacht installation windproof wall, installation of windproof wall near the bow and stern lifesaving valve, and so on.

The crew sometimes needs to work in a room in an open area (such as a winch space). In order to operate the normal equipment in a relatively comfortable environment, a space heater is required to be installed in the room to prevent freezing. It can be used as an electric heater and calculates the power of the antifreeze space heater.

The escape channel is an important safety setting. In order to ensure effective identification and use of escape passages under severe cold, the activities and evacuation of personnel are not affected by the ice. According to DNV winterization basic, the escape passage in the open area belongs to the I type antifreeze area, which requires that the area can't have ice accumulation. Heat tracing is usually used to achieve the above purpose. Electric tracing has the advantages of simple installation, uniform heat dissipation, accurate temperature, high reliability, long service life, and energy saving (Guo and Li 2002).

In the layout of polar offshore platforms, the influence of low-temperature weather on the piping system should be considered in order to avoid the occurrence of liquid icing in the piping system. In carrying out piping layout, we should pay attention to the following aspects (Yang 2015):

1. As far as piping system is concerned, try to avoid direct exposure to outdoor lines below the waterline.
2. Discharge pipes shall be installed on icing pipes on the open deck and above the waterline.
3. It is necessary to increase the diameter of the drainage pipeline in the open area to avoid blockage.
4. For water tanks above the waterline, heating pipes should be added to prevent freezing.

Interior Antifreeze Design

The objective of interior antifreeze design for polar offshore platforms is to ensure that under harsh weather conditions, the living conditions of the platform personnel and the normal operation of the equipment are satisfied. The indoor antifreeze of the platform is mainly realized by heating, ventilation, and air conditioning system, and the three are collectively referred to as HVAC system.

The heating system of polar offshore platform can be divided into two parts: mechanical area and living area. Because the air conditioning in residential areas has the function of heating, the heating of living areas is a part of the air conditioning system. The main purpose of mechanical zone heating is to protect equipment and pipelines in low-temperature environment, and the way to use them is to use space heaters. The main function of the platform air conditioning system is to make the air to the required state, that is, the air temperature, humidity, air flow speed, and cleanliness are manually adjusted to meet the requirements of human comfort and process production (Yang 2015).

Design of Heat Source System

The heat source system is mainly used for the heating of fuel, oil, and other kinds of liquid needed by the power plant and provides the heat source for the heating equipment such as the cabin air conditioner and the heater. Therefore, the heat source system is one of the important systems of polar offshore platforms. The heat source system can be divided into four types according to the working fluids: steam heating system, hot water heating system, hot oil system, and electric heating system.

Steam heating has a simple and cheap working substance (water) and is widely used in heating occasions when experience is mature. There are three main types of steam users: room heating, cabin heating, and equipment heating. The hot water in the hot water heating system has a low temperature and a large flow rate. If the heating medium of the heating coil of the air conditioner is changed into hot water, the steady flow of water can be kept in the heating coil, and the danger of

the freezing cracking of the heating coil can be reduced. In the actual use of hot water heating systems, antifreeze may be added to hot water (Yang 2015).

Coating Protection

The special surface materials on the bare surface of polar offshore platforms can also effectively prevent icing, such as sacrificial coatings, superhydrophobic coatings, and water-lubricated coatings.

The sacrificial coating can release some small molecules that inhibit the crystallization of supercooled water irreversible and increase the lubricity of ice and material surface, reduce the adhesion strength of ice, and even make the icing naturally fall off (Ayres et al. 2007).

The so-called superhydrophobic coating is the coating with water contact angle greater than 150° and the rolling angle less than 10° . The coating has the dual properties of the surface and the multilevel roughness of the low surface energy material, which can reduce the contact area of water or ice to the material surface, enhance the stress concentration of the ice and the material interface, and reduce the adhesion shear strength of the ice. So as to achieve the purpose of delaying icing, and after freezing, the ice adhering to the surface of the coating can be removed by very small force or wind. Meuler et al. have studied the relationship between the ice adhesion strength of a series of materials and the water back contact angle θ_{rec} . It is found that the ice adhesion strength is strongly correlated with $1 + \cos\theta_{\text{rec}}$. The results show that increasing the water back contact angle of the coating helps to reduce the ice adhesion strength and has guiding significance for the design of superhydrophobic anti-icing coating (Meuler et al. 2010).

Dou et al. (2014) graft hydrophilic dimethyl hydroxypropionic acid (DMPA) onto polyurethane (PU) substrate to make the coating hydrophilic. The contact angle is only 43° . The mechanism is to separate the ice and the coating

surface by absorbing moisture. At -15°C , the adhesion strength of ice can be reduced to below 30 kPa.
